8 Abstract 1

9 Flood damage reflects insufficient adaptation of human presence and activity to
10 location and variability (inherent plus induced) of river flow. Increased variability and
11 reduced predictability of river flow is a common sign, in public discourse, of
12 degrading watersheds, combining increased flooding risk and reduced low flows. Flow
13 buffering in landscapes is commonly interpreted as ecosystem service, but needs
14 quantification. Geology, landscape form, soil porosity, litter layer and surface features,
15 drainage pathways, vegetation and space-time patterns of rainfall interact in complex
16 space-time patterns of riverflow, but the anthropogenic aspects tend to get discussed
17 on a one-dimensional scale of degradation and restoration. A strong tradition in public
18 discourse associates changes on such degradation-restoration axis with changes in tree
19 cover and/or forest quality, but the empirical evidence for such link that may exist at
20 high spatial resolution may not be a safe basis for securing required flow buffering in
21 landscapes at large. Capturing the relationship between the space-time patterns of
22 rainfall and riverflow in a single buffering indicator can help the way empirical
23 evidence is summarized and projected change in land use change scenarios is
24 evaluated. Where space-time details of rainfall remain unknown, a simpler approach is
25 needed. We present and discuss a candidate here for a single parameter representation
26 of the complex concept of watershed quality that does align short and long term
27 responses, and provides bounds to the levels of unpredictability. The dimensionless
28 FlowPer parameter (F_p) represents predictability of river flow. It is defined through a
29 recursive model of river flow, $Q_t = F_p Q_{t-1} + (1-F_p)(P_t - E_{tx})$, that relates the flow Q on
30 day t to that on the previous day (Q_{t-1}), and a term that reflects precipitation P on the
31 day itself and evapotranspiration E in a preceding time period, with Q , P and E
32 expressed in mm d^{-1} . When summed over one or more years, this recursive model
33 reflects the water balance ($\sum Q = \sum P - \sum E$), once changes in the storage term that can
34 dominate short term dynamics become negligible. F_p varies between 0 and 1, and can
35 be derived from a time-series of measured (or modeled) river flow data. In a
36 parsimonious interpretation that aligns with data sets that only exist of (daily) records
37 of riverflow, the spatially averaged precipitation term P_t and preceding cumulative
38 evapotranspiration since previous rain E_{tx} are treated as constrained but unknown,
39 stochastic variables. Without knowing when peak flows occur, the balance equation

40 suggests that a decrease in F_p from 0.9 to 0.8 means peak flow doubling from 10 to
41 20% of peak rainfall (minus its accompanying E_{tx}). Flood duration has a nonlinear
42 response to increases in F_p , as low F_p values lead to high peak flow of short duration,
43 and at high F_p values thresholds of flooding may never be reached. In a numerical
44 example a decrease in F_p led at most to an increase in expected flood duration by 3
45 days. As a potential indicator of watershed health (or quality), the F_p metric (or its
46 change over time from what appears to be the local norm) matches local knowledge
47 concepts, captures key aspects of the river flow dynamic and can be unambiguously
48 derived from empirical river flow data. Further exploration of responsiveness of F_p to
49 the interaction of land cover and the specific realization of space-time patterns of
50 rainfall in a limited observation period is needed to test the interpretation of F_p as
51 indicator of watershed health (or quality) in the way this is degrading or restoring
52 through land cover change and modifications of the overland and surface flow
53 pathways, given inherent properties such as geology, geomorphology and climate.

54 **1 Introduction**

55 Degradation of watersheds and its consequences for river flow regime and flooding intensity
56 and frequency are a widespread concern (Brauman et al., 2007; Bishop and Pagiola, 2012;
57 Winsemius et al., 2013). Current watershed rehabilitation programs that focus on increasing
58 tree cover in upper watersheds are only partly aligned with current scientific evidence of
59 effects of large-scale tree planting on streamflow (Ghimire et al., 2014; Malmer et al., 2010;
60 Palmer, 2009; van Noordwijk et al., 2007, 2015a; Verbist et al 2010). The relationship
61 between floods and change in forest quality and quantity, and the availability of evidence for
62 such a relationship at various scales has been widely discussed over the past decades
63 (Andréassian, 2004; Bruijnzeel, 2004; Bradshaw et al., 2007; van Dijk et al., 2009).
64 Measurements in Cote d'Ivoire, for example, showed strong scale dependence of runoff from
65 30-50% at 1 m² point scale, to 4% at 130 ha watershed scale, linked to spatial variability of
66 soil properties plus variations in rainfall patterns (Van de Giesen et al., 2000). The ratio
67 between peak and average flow decreases from headwater streams to main rivers in a
68 predictable manner; while mean annual discharge scales with (area)^{1.0}, maximum river flow
69 was found to scale with (area)^{0.7} on average (Rodríguez-Iturbe and Rinaldo, 2001; van
70 Noordwijk et al., 1998). The determinants of peak flows are thus scale-dependent, with space-
71 time correlations in rainfall interacting with subcatchment-level flow buffering in peakflows

72 at any point along the river. Whether and where peakflows lead to flooding depends on the
73 capacity of the rivers to pass on peakflows towards downstream lakes or the sea, assisted by
74 riparian buffer areas with sufficient storage capacity (Baldassarre et al., 2013); reducing local
75 flooding risk by increased drainage increases flooding risk downstream, challenging the
76 nested-scales management of watersheds to find an optimal spatial distribution, rather than
77 minimization, of flooding probabilities. Well-studied effects of forest conversion on peak
78 flows in small upper stream catchments (Alila et al., 2009) do not necessarily translate to
79 flooding downstream. As summarized by Beck et al. (2013) meso- to macroscale catchment
80 studies (>1 and $>10\,000$ km², respectively) in the tropics, subtropics, and warm temperate
81 regions have mostly failed to demonstrate a clear relationship between river flow and change
82 in forest area. Lack of evidence cannot be firmly interpreted as evidence for lack of effect,
83 however. A recent econometric study for Peninsular Malaysia by Tan-Soo et al. (2014)
84 concluded that, after appropriate corrections for space-time correlates in the data-set for 31
85 meso- and macroscale basins (554-28,643 km²), conversion of inland rain forest to
86 monocultural plantations of oil palm or rubber increased the number of flooding days
87 reported, but not the number of flood events, while conversion of wetland forests to urban
88 areas reduced downstream flood duration. This Malaysian study may be the first credible
89 empirical evidence at this scale. The difference between results for flood duration and flood
90 frequency and the result for draining wetland forests warrant further scrutiny. Consistency of
91 these findings with river flow models based on a water balance and likely pathways of water
92 under the influence of change in land cover and land use has yet to be shown. Two recent
93 studies for Southern China confirm the conventional perspective that deforestation increases
94 high flows, but are contrasting in effects of reforestation. Zhou et al. (2010) analyzed a 50-
95 year data set for Guangdong Province in China and concluded that forest recovery had not
96 changed the annual water yield (or its underpinning water balance terms precipitation and
97 evapotranspiration), but had a statistically significant positive effect on dry season (low)
98 flows. Liu et al. (2015), however, found for the Meijiang watershed (6983 km²) in
99 subtropical China that while historical deforestation had decreased the magnitudes of low
100 flows (daily flows $\leq Q_{95\%}$) by 30.1%, low flows were not significantly improved by
101 reforestation. They concluded that recovery of low flows by reforestation may take much
102 longer time than expected probably because of severe soil erosion and resultant loss of soil
103 infiltration capacity after deforestation. Changes in riverflow patterns over a limited period of
104 time can be the combined and interactive effects of variations in the local rainfall regime, land

105 cover effects on soil structure and engineering modifications of water flow, that can be teased
106 apart with modelling tools (Ma et al., 2014).

107 Lacombe et al. (2015) documented that the hydrological effects of natural regeneration differ
108 from those of plantation forestry, while forest statistics don't normally differentiate between
109 these different land covers. In a regression study of the high and low flow regimes in the
110 Volta and Mekong river basins Lacombe and McCartney (2016) found that in the variation
111 among tributaries various aspects of land cover and land cover change had explanatory power.
112 Between the two basins, however, these aspects differed. In the Mekong basin variation in
113 forest cover had no direct effect on flows, but extending paddy areas resulted in a decrease in
114 downstream low flows, probably by increasing evapotranspiration in the dry season. In the
115 Volta River Basin, the conversion of forests to crops (or a reduction of tree cover in the
116 existing parkland system) induced greater downstream flood flows. This observation is
117 aligned with the experimental identification of an optimal, intermediate tree cover from the
118 perspective of groundwater recharge in parklands in Burkina Faso (Ilstedt et al., 2016).

119 The statistical challenges of attribution of cause and effect in such data-sets are considerable
120 with land use/land cover interacting with spatially and temporally variable rainfall, geological
121 configuration and the fact that land use is not changing in random fashion or following any
122 pre-randomized design (Alila et al., 2009; Rudel et al., 2005). Hydrological analysis across
123 12 catchments in Puerto Rico by Beck et al. (2013) did not find significant relationships
124 between the change in forest cover or urban area, and change in various flow characteristics,
125 despite indications that regrowing forests increased evapotranspiration. Yet, the concept of a
126 'regulating function' on river flow regime for forests and other semi-natural ecosystems is
127 widespread. The considerable human and economic costs of flooding at locations and times
128 beyond where this is expected make the presumed 'regulating function' on flood reduction of
129 high value (Brauman et al., 2007) – if only we could be sure that the effect is real, beyond the
130 local scales ($< 10 \text{ km}^2$) of paired catchments where ample direct empirical proof exists
131 (Bruijnzeel, 1990, 2004). These observations imply that percent tree cover (or other forest
132 related indicators) is probably not a good metric for judging the ecosystem services provided
133 by a watershed (of different levels of 'health'), and that a metric more directly reflecting
134 changes in river flow may be needed. Here we will explore a simple recursive model of river
135 flow (van Noordwijk et al., 2011) that (i) is focused on (loss of) predictability, (ii) can
136 account for the types of results obtained by the cited recent Malaysian study (Tan-Soo et al.,

137 2014), and (iii) may constitute a suitable performance indicator to monitor watershed ‘health’
138 through time.

139 ⇒ Fig. 1

140 Figure 1 is compatible with a common dissection of risk as the product of hazard, exposure
141 and vulnerability. Extreme discharge events plus river-level engineering co-determine hazard,
142 while exposure depends on topographic position interacting with human presence, and
143 vulnerability can be modified by engineering at a finer scale and be further reduced by advice
144 to leave an area in high-risk periods. A recent study (Jongman et al., 2015) found that human
145 fatalities and material losses between 1980 and 2010 expressed as a share of the exposed
146 population and gross domestic product were decreasing with rising income. The planning
147 needed to avoid extensive damage requires quantification of the risk of higher than usual
148 discharges, especially at the upper tail end of the flow frequency distribution.

149 The statistical scarcity, per definition, of ‘extreme events’ and the challenge of data collection
150 where they do occur, make it hard to rely on empirical data as such. Existing data on flood
151 frequency and duration, as well as human and economic damage are influenced by
152 topography, human population density and economic activity, interacting with engineered
153 infrastructure (step 4 and 5 in Fig. 1), as well as the extreme rainfall events that are their
154 proximate cause. Subsidence due to groundwater extraction in urban areas of high population
155 density is a specific problem for a number of cities built on floodplains (such as Jakarta and
156 Bangkok), but subsidence of drained peat areas has also been found to increase flooding risks
157 elsewhere (Sumarga et al., 2016). Common hydrological analysis of flood frequency (called 1
158 in 10-, 1 in 100-, 1 in 1000-year flood events, for example) does not separately attribute
159 flood magnitude to rainfall and land use properties, and analysis of likely change in flood
160 frequencies in the context of climate change adaptation has been challenging (Milly et al.,
161 2002; Ma et al., 2014). There is a lack of simple performance indicators for watershed health
162 at its point of relating precipitation P and river flow Q (step 2 in Fig. 1) that align with local
163 observations of river behavior and concerns about its change and that can reconcile local,
164 public/policy and scientific knowledge, thereby helping negotiated change in watershed
165 management (Leimona et al., 2015). The behavior of rivers depends on many climatic (step 1
166 in Figure 1) and terrain factors (step 7-9 in Figure 1) that make it a challenge to differentiate
167 between anthropogenically induced ecosystem structural change and soil degradation (step
168 7a) on one hand and intrinsic variability on the other. Arrow 10 in Figure 1 represents the
169 direct influence of climate on vegetation, but also a possible reverse influence (van Noordwijk

170 et al., 2015b). Hydrological models tend to focus on predicting hydrographs at one or more
171 temporal scales, and are usually tested on data-sets from limited locations. Despite many
172 decades (if not centuries) of hydrological modeling, current hydrologic theory, models and
173 empirical methods have been found to be largely inadequate for sound predictions in
174 ungauged basins (Hrachowitz et al., 2013). Efforts to resolve this through harmonization of
175 modelling strategies have so far failed. Existing models differ in the number of explanatory
176 variables and parameters they use, but are generally dependent on empirical data of rainfall
177 that are available for specific measurement points but not at the spatial resolution that is
178 required for a close match between measured and modeled river flow. Spatially explicit
179 models have conceptual appeal (Ma et al., 2010) but have too many degrees of freedom and
180 too many opportunities for getting right answers for wrong reasons if used for empirical
181 calibration (Beven, 2011). Parsimonious, parameter-sparse models are appropriate for the
182 level of evidence available to constrain them, but these parameters are themselves implicitly
183 influenced by many aspects of existing and changing features of the watershed, making it
184 hard to use such models for scenario studies of interacting land use and climate change. Here
185 we present a more direct approach deriving a metric of flow predictability that can bridge
186 local concerns and concepts to quantified hydrologic function: the ‘flow persistence’
187 parameter (step 2 in Figure 1).

188 In this contribution to the debate we will first define the metric ‘flow persistence’ in the
189 context of temporal autocorrelation of river flow and then derive a way to estimate its
190 numerical value. In part II we will apply the algorithm to river flow data for a number of
191 contrasting meso-scale watersheds. In the discussion of this paper we will consider the new
192 flow persistence metric in terms of three groups of criteria for usable knowledge (Clark et al.,
193 2011; Lusiana et al., 2011; Leimona et al., 2015) based on salience (1,2), credibility (3,4) and
194 legitimacy (5-7):

- 195 1. Does flow persistence relate to important aspects of watershed behavior?
- 196 2. Does it’s quantification help to select management actions?
- 197 3. Is there consistency of numerical results?
- 198 4. How sensitive is it to bias and random error in data sources?
- 199 5. Does it match local knowledge?
- 200 6. Can it be used to empower local stakeholders of watershed management?

201 7. Can it inform local risk management?

202 Questions 3 and 4 will get specific attention in part II.

203 **2 Recursive river flow model and flow persistence**

204 **2.1 Basic equations**

205 One of the easiest-to-observe aspects of a river is its day-to-day fluctuation in waterlevel,
206 related to the volumetric flow (discharge) via rating curves (Maidment, 1992). Without
207 knowing details of upstream rainfall and the pathways the rain takes to reach the river,
208 observation of the daily fluctuations in waterlevel allows important inferences to be made. It
209 is also of direct utility: sudden rises can lead to floods without sufficient warning, while rapid
210 decline makes water utilization difficult. Indeed, a common local description of watershed
211 degradation is that rivers become more ‘flashy’ and less predictable, having lost a buffer or
212 ‘sponge’ effect (Joshi et al., 2004; Ranieri et al., 2004; Rahayu et al., 2013). The probably
213 simplest model of river flow at time t , Q_t , is that it is similar to that of the day before (Q_{t-1}), to
214 the degree F_p , a dimensionless parameter called ‘flow persistence’ (van Noordwijk et al.,
215 2011) plus an additional stochastic term $Q_{a,t}$:

$$216 \quad Q_t = F_p Q_{t-1} + Q_{a,t} \quad [1].$$

217 Q_t is for this analysis expressed in mm d^{-1} , which means that measurements in $\text{m}^3 \text{s}^{-1}$ need to
218 be divided by the relevant catchment area, with appropriate unit conversion. If river flow were
219 constant, it would be perfectly predictable, i.e. F_p would be 1.0 and $Q_{a,t}$ zero; in contrast, an
220 F_p -value equal to zero and $Q_{a,t}$ directly reflecting erratic rainfall represents the lowest possible
221 level of predictability.

222 The F_p parameter is conceptually identical to the ‘recession constant’ commonly used in
223 hydrological models, typically assessed during an extended dry period when the $Q_{a,t}$ term is
224 negligible and streamflow consists of baseflow only (Tallaksen, 1995); empirical deviations
225 from a straight line in a plot of the logarithm of Q against time are common and point to
226 multiple rather than a single groundwater pool that contributes to base flow. With increasing
227 size of a catchment area it is increasingly likely that there indeed are multiple, partly
228 independent groundwater contributions.

229 As we will demonstrate in a next section, it is possible to derive F_p even when $Q_{a,t}$ is not
 230 negligible. In climates without distinct dry season this is essential; elsewhere it allows a
 231 comparison of apparent F_p between wet and dry parts of the hydrologic year. A possible
 232 interpretation, to be further explored, is that decrease over the years of F_p indicates ‘watershed
 233 degradation’ (i.e. greater contrast between high and low flows), and an increase
 234 ‘improvement’ or ‘rehabilitation’ (i.e. more stable flows).

235 If we consider the sum of river flow over a period of time (from 1 to T) we obtain

$$236 \quad \Sigma_1^T Q_t = F_p \Sigma_1^T Q_{t-1} + \Sigma_1^T Q_{a,t} \quad [2].$$

237 If the period is sufficiently long period for Q_T minus Q_0 to be negligibly small relative to the
 238 sum over all t’s, we may equate $\Sigma_1^T Q_t$ with $\Sigma_1^T Q_{t-1}$ and obtain a first way of estimating the F_p
 239 value:

$$240 \quad F_p = 1 - \Sigma_1^T Q_{a,t} / \Sigma_1^T Q_t \quad [3].$$

241 Rearranging Eq.(3) we obtain

$$242 \quad \Sigma_1^T Q_{a,t} = (1 - F_p) \Sigma_1^T Q_t \quad [4].$$

243 The F_p term is equivalent with one of several ways to separate baseflow from peakflows. The
 244 $\Sigma Q_{a,t}$ term reflects the sum of peak flows in mm, while $F_p \Sigma Q_t$ reflects the sum of base flow,
 245 also in mm. For $F_p = 1$ (the theoretical maximum) we conclude that all $Q_{a,t}$ must be zero, and
 246 all flow is ‘base flow’.

247 The stochastic $Q_{a,t}$ can be interpreted in terms of what hydrologists call ‘effective rainfall’
 248 (i.e. rainfall minus on-site evapotranspiration, assessed over a preceding time period t_x since
 249 previous rain event):

$$250 \quad Q_t = F_p Q_{t-1} + (1-F_p)(P_{t_x} - E_{t_x}) \quad [5].$$

251 Where P_{t_x} is the (spatially weighted) precipitation (assuming no snow or ice, which would
 252 shift the focus to snowmelt) in mm d^{-1} ; E_{t_x} , also in mm d^{-1} , is the preceding
 253 evapotranspiration that allowed for infiltration during this rainfall event (i.e.
 254 evapotranspiration since the previous soil-replenishing rainfall that induced empty pore space
 255 in the soil for infiltration and retention), or replenishment of a waterfilm on aboveground
 256 biomass that will subsequently evaporate. More complex attributions are possible, aligning
 257 with the groundwater replenishing bypassflow and the water isotopic fractionation involved
 258 in evaporation (Evaristo et al., 2015).

259 The consistency of multiplying effective rainfall with $(1-F_p)$ can be checked by considering
 260 the geometric series $(1-F_p)$, $(1-F_p) F_p$, $(1-F_p) F_p^2$, ..., $(1-F_p) F_p^n$ which adds up to $(1-F_p)(1 -$
 261 $F_p^n)/(1-F_p)$ or $1 - F_p^n$. This approaches 1 for large n , suggesting that all of the water attributed
 262 to time t , *i.e.* $P_t - E_{tx}$, will eventually emerge as river flow. For $F_p = 0$ all of $(P_t - E_{tx})$ emerges
 263 on the first day, and riverflow is as unpredictable as precipitation itself. For $F_p = 1$ all of $(P_t -$
 264 $E_{tx})$ contributes to the stable daily flow rate, and it takes an infinitely long period of time for
 265 the last drop of water to get to the river. For declining F_p , ($1 > F_p > 0$), river flow gradually
 266 becomes less predictable, because a greater part of the stochastic precipitation term
 267 contributes to variable rather than evened-out river flow.

268 Taking long term summations of the right- and left- hand sides of Eq.(5) we obtain:

$$269 \quad \Sigma Q_t = \Sigma (F_p Q_{t-1} + (1-F_p)(P_t - E_{tx})) = F_p \Sigma Q_{t-1} + (1-F_p)(\Sigma P_t - \Sigma E_{tx}) \quad [6].$$

270 Which is consistent with the basic water budget, $\Sigma Q = \Sigma P - \Sigma E$, at time scales long enough
 271 for changes in soil water buffer stocks to be ignored. As such the total annual, and hence the
 272 mean daily river flow are independent of F_p . This does not preclude that processes of
 273 watershed degradation or restoration that affect the partitioning of P over Q and E also affect
 274 F_p .

275 **2.2 Low flows**

276 The lowest flow expected in an annual cycle is $Q_x F_p^{N_{max}}$ where Q_x is flow on the first day
 277 without rain and N_{max} the longest series of dry days. Taken at face value, a decrease in F_p has
 278 a strong effect on low-flows, with a flow of 10% of Q_x reached after 45, 22, 14, 10, 8 and 6
 279 days for $F_p = 0.95, 0.9, 0.85, 0.8, 0.75$ and 0.7 , respectively. However, the groundwater
 280 reservoir that is drained, equalling the cumulative dry season flow if the dry period is
 281 sufficiently long, is $Q_x/(1-F_p)$. If F_p decreases to F_{px} but the groundwater reservoir ($Res =$
 282 $Q_x/(1-F_p)$) is not affected, initial flows in the dry period will be higher ($Q_x F_{px}^i (1-F_{px}) Res >$
 283 $Q_x F_p^i (1-F_p) Res$ for $i < \log((1-F_{px})/(1-F_p))/\log(F_p/F_{px})$). It thus matters how low flows are
 284 evaluated: from the perspective of the lowest level reached, or as cumulative flow. The
 285 combination of climate, geology and land form are the primary determinants of cumulative
 286 low flows, but if land cover reduces the recharge of groundwater there may be impacts on dry
 287 season flow, that are not directly reflected in F_p .

288 If a single F_p value would account for both dry and wet season, the effects of changing F_p on
 289 low flows may well be more pronounced than those on flood risk. Empirical tests are needed

290 of the dependence of F_p on Q (see below). Analysis of the way an aggregate F_p depends on
291 the dominant flow pathways provides a basis for differentiating F_p within a hydrologic year.

293 **2.3 Flow-pathway dependence of flow persistence**

294 The patch-level partitioning of water between infiltration and overlandflow is further
295 modified at hillslope level, with a common distinction between three pathways that reach
296 streams: overland flow, interflow and groundwater flow (Band et al., 1993; Weiler and
297 McDonnell, 2004). An additional interpretation of Eq.(1), potentially adding to our
298 understanding of results but not needed for analysis of empirical data, can be that three
299 pathways of water through a landscape contribute to river flow (Barnes, 1939): groundwater
300 release with $F_{p,g}$ values close to 1.0, overland flow with $F_{p,o}$ values close to 0, and interflow
301 with intermediate $F_{p,i}$ values.

$$302 \quad Q_t = F_{p,g} Q_{t-1,g} + F_{p,i} Q_{t-1,i} + F_{p,o} Q_{t-1,o} + Q_{a,t} \quad [7],$$

$$303 \quad F_p = (F_{p,g} Q_{t-1,g} + F_{p,i} Q_{t-1,i} + F_{p,o} Q_{t-1,o}) / Q_{t-1} \quad [8].$$

304 On this basis a decline or increase in overall weighted average F_p can be interpreted as
305 indicator of a shift of dominant runoff pathways through time within the watershed. Dry
306 season flows are dominated by $F_{p,g}$. The effective F_p in the rainy season can be interpreted as
307 indicating the relative importance of the other two flow pathways. F_p reflects the fractions of
308 total river flow that are based on groundwater, overland flow and interflow pathways:

$$309 \quad F_p = F_{p,g} (\sum Q_{t,g} / \sum Q_t) + F_{p,o} (\sum Q_{t,o} / \sum Q_t) + F_{p,i} (\sum Q_{t,i} / \sum Q_t) \quad [9].$$

310 Beyond the type of degradation of the watershed that, mostly through soil compaction, leads
311 to enhanced infiltration-excess (or Hortonian) overland flow (Delfs et al., 2009), saturated
312 conditions throughout the soil profile may also induce overland flow, especially near valley
313 bottoms (Bonell, 1993; Bruijnzeel, 2004). Thus, the value of $F_{p,o}$ can be substantially above
314 zero if the rainfall has a significant temporal autocorrelation, with heavy rainfall on
315 subsequent days being more likely than would be expected from general rainfall frequencies.
316 If rainfall following a wet day is more likely to occur than following a dry day, as is
317 commonly observed in Markov chain analysis of rainfall patterns (Jones and Thornton, 1997;
318 Bardossy and Plate, 1991), the overland flow component of total flow will also have a partial
319 temporal autocorrelation, adding to the overall predictability of river flow. In a hypothetical
320 climate with evenly distributed rainfall, we can expect F_p to be 1.0 even if there is no

321 infiltration and the only pathway available is overland flow. Even with rainfall that is variable
322 at any point of observation but has low spatial correlation it is possible to obtain F_p values of
323 (close to) 1.0 in a situation with (mostly) overland flow (Ranieri et al., 2004).

324 **3. Methods**

325 **3.1 Numerical example**

326 Figure 2 provides an example of the way a change in F_p values (based on Eq. 1) influences the
327 visual pattern of river flow for a unimodal rainfall regime with a well-developed dry season.
328 The increasing ‘spikedness’ of the graph as F_p is lowered indicates reduced predictability of
329 flow on any given day during the wet season on the basis of the flow on the preceding day. A
330 bi-plot of river flow on subsequent days for the same simulations (Fig. 3) shows two main
331 effects of reducing the F_p value: the scatter increases, and the slope of the lower envelope
332 containing the swarm of points is lowered (as it equals F_p). Both of these changes can provide
333 entry points for an algorithm to estimate F_p from empirical time series, provided the basic
334 assumptions of the simple model apply and the data are of acceptable quality (see Section 3
335 below). For the numerical example shown in Fig. 2, the maximum daily flow doubled from 50
336 to 100 mm when the F_p value decreased from a value close to 1 (0.98) to nearly 0.

337 ⇒ Fig. 2

338 ⇒ Fig. 3

339 **3.2 Flow persistence as a simple flood risk indicator**

340 For numerical examples (implemented in a spreadsheet model) flow on each day can be
341 derived as:

$$342 \quad Q_t = \sum_j^t F_p^{t-j} (1-F_p) p_j P_j \quad [10].$$

343 Where p_j reflects the occurrence of rain on day j (reflecting a truncated sine distribution for
344 seasonal trends) and P_j is the rain depth (drawn from a uniform distribution). From this model
345 the effects of F_p (and hence of changes in F_p) on maximum daily flow rates, plus maximum
346 flow totals assessed over a 2-5 d period, was obtained in a Monte Carlo process (without
347 Markov autocorrelation of rainfall in the default case – see below). Relative flood protection
348 was calculated as the difference between peak flows (assessed for 1-5 d duration after a 1 year
349 ‘warm-up’ period) for a given F_p versus those for $F_p = 0$, relative to those at $F_p = 0$.

350 **3.3 An algorithm for deriving F_p from a time series of stream flow data**

351 Equation (3) provides a first method to derive F_p from empirical data if these cover a full
352 hydrologic year. In situations where there is no complete hydrograph and/or in situations
353 where we want to quantify F_p for shorter time periods (e.g. to characterise intraseasonal flow
354 patterns) and the change in the storage term of the water budget equation cannot be ignored,
355 we need an algorithm for estimating F_p from a series of daily Q_t observations.

356 Where rainfall has clear seasonality, it is attractive and indeed common practice to derive a
357 groundwater recession rate from a semi-logarithmic plot of Q against time (Tallaksen, 1995).
358 As we can assume for such periods that $Q_{a,t} = 0$, we obtain $F_p = Q_t / Q_{t-1}$, under these
359 circumstances. We cannot be sure, however, that this $F_{p,g}$ estimate also applies in the rainy
360 season, because overall wet-season F_p will include contributions by $F_{p,o}$ and $F_{p,i}$ as well
361 (compare Eq. 9). In locations without a distinct dry season, we need an alternative method.

362 A biplot of Q_t against Q_{t-1} (as in Fig. 3) will lead to a scatter of points above a line with slope
363 F_p , with points above the line reflecting the contributions of $Q_{a,t} > 0$, while the points that plot
364 on the F_p line itself represent $Q_{a,t} = 0 \text{ mm d}^{-1}$. There is no independent source of information
365 on the frequency at which $Q_{a,t} = 0$, nor what the statistical distribution of $Q_{a,t}$ values is if it is
366 non-zero. Calculating back from the Q_t series we can obtain an estimate ($Q_{a,Fptry}$) of $Q_{a,t}$ for
367 any given estimate ($F_{p,try}$) of F_p , and select the most plausible F_p value. For high $F_{p,try}$
368 estimates there will be many negative $Q_{a,Fptry}$ values, for low $F_{p,try}$ estimates all $Q_{a,Fptry}$ values
369 will be larger. An algorithm to derive a plausible F_p estimate can thus make use of the
370 corresponding distribution of ‘apparent Q_a ’ values as estimates of $F_{p,try}$, calculated as $Q_{a,try} =$
371 $Q_t - F_{p,try} Q_{t-1}$. While $Q_{a,t}$ cannot be negative in theory, small negative Q_a estimates are likely
372 when using real-world data with their inherent errors. The FlowPer F_p algorithm (van
373 Noordwijk et al., 2011) derives the distribution of $Q_{add,Fptry}$ estimates for a range of $F_{p,try}$
374 values (Fig. 4B) and selects the value $F_{p,try}$ that minimizes the variance $\text{Var}(Q_{a,Fptry})$ (or its
375 standard deviation) (Fig. 4C). It is implemented in a spreadsheet workbook that can be
376 downloaded from the ICRAF website ([http://www.worldagroforestry.org/output/flowper-](http://www.worldagroforestry.org/output/flowper-flow-persistence-model)
377 [flow-persistence-model](http://www.worldagroforestry.org/output/flowper-flow-persistence-model))

378 →Fig. 4

379 A consistency test is needed that the high-end Q_t values relate to Q_{t+1} in the same way as do
380 low or medium Q_t values. Visual inspection of Q_{t+1} versus Q_t , with the derived F_p value,
381 provides a qualitative view of the validity of this assumption. The F_p algorithm can be applied

382 to any population of (Q_{t-1}, Q_t) pairs, e.g. selected from a multiyear data set on the basis of 3-
383 month periods within the hydrological year.

384 **4 Results**

385 **4.1 Flood intensity and duration**

386 Figure 5 shows the effect of F_p values in the range 0 to 1 on the maximum flows obtained
387 with a random time series of ‘effective rainfall’, compared to results for $F_p = 0$. Maximum
388 flows were considered at time scales of 1 to 5 days, in a moving average routine. This way a
389 relative flood protection, expressed as reduction of peak flow, could be related to F_p (Fig.
390 5A).

391 ⇒ Fig. 5

392 Relative flood protection rapidly decreased from its theoretical value of 100% at $F_p = 1$ (when
393 there was no variation in river flow), to less than 10% at F_p values of around 0.5. Relative
394 flood protection was slightly lower when the assessment period was increased from 1 to 5
395 days (between 1 and 3 d it decreased by 6.2%, from 3 to 5 d by a further 1.3%). Two
396 counteracting effects are at play here: a lower F_p means that a larger fraction $(1-F_p)$ of the
397 effective rainfall contributes to river flow, but the increased flow is less persistent. In the
398 example the flood protection in situations where the rainfall during 1 or 2 d causes the peak is
399 slightly stronger than where the cumulative rainfall over 3-5 d causes floods, as typically
400 occurs downstream.

401 As we expect from equation 5 that peak flow is to $(1-F_p)$ times peak rainfall amounts, the
402 effect of a change in F_p not only depends on the change in F_p that we are considering, but also
403 on its initial value. Higher initial F_p values will lead to more rapid increases in high flows for
404 the same reduction in F_p (Fig. 5B). However, flood duration rather responds to changes in F_p
405 in a curvilinear manner, as flow persistence implies flood persistence (once flooding occurs),
406 but the greater the flow persistence the less likely such a flooding threshold is passed (Fig.
407 5C). The combined effect may be restricted to about 3 d of increase in flood duration for the
408 parameter values used in the default example, but for different parametrization of the
409 stochastic ε other results might be obtained.

410 **4.2 Algorithm for F_p estimates from river flow time series**

411 The algorithm has so far returned non-ambiguous F_p estimates on any modelled time series
412 data of river flow, as well as for all empirical data set we tested (including all examples tested
413 in part II), although there probably are data sets on which it can breakdown. Visual inspection
414 of Q_{t-1}/Q_t biplots (as in Fig. 3) can provide clues to non-homogenous data sets, and to
415 potential situations where effective F_p depends on flow level Q_t and where data are not
416 consistent with a straight-line lower envelope. Where river flow estimates were derived from a
417 model with random elements, however, variation in F_p estimates was observed, that suggests
418 that specific aspects of actual rainfall, beyond the basic characteristics of a watershed and its
419 vegetation, do have at least some effect. Such effects deserve to be further explored for a set
420 of case studies, as their strength probably depends on context.

421 **5 Discussion**

422 We will discuss the flow persistence metric based on the questions raised from the
423 perspectives of salience, credibility and legitimacy.

424 **5.1 Salience**

425 Key *salience* aspects are “Does flow persistence relate to important aspects of watershed
426 behavior?” and “Does it help to select management actions?”. A major finding in the
427 derivation of F_p was that the flow persistence measured at daily time scale can be logically
428 linked to the long-term water balance, and that the proportion of peak rainfall that translates to
429 peak river flow equals the complement of flow persistence. This feature links effects on
430 floods of changes in watershed quality to effects on low flows, although not in a linear
431 relationship. The F_p parameter as such does not predict when and where flooding will occur,
432 but it does help to assess to what extent another condition of the watershed, with either higher
433 or lower F_p would translate the same rainfall into larger or small peak waterflows. This is
434 salient, especially if the relative contributions of (anthropogenic) land cover and the
435 (exogenous, probabilistic) specifics of the rainfall pattern can be further teased apart (see part
436 II). Where F_p may describe the descending branch of hydrographs at a relevant time scale,
437 details of the ascending branch beyond the maximum daily flow reached may be relevant for
438 reducing flood damage, and may require more detailed study at higher temporal resolution.

439 A key strength of our flow persistence parameter, that it can be derived from observing river
440 flow at a single point along the river, without knowledge of rainfall events and catchment
441 conditions, is also its major weakness. If rainfall data exist, and especially rainfall data that
442 apply to each subcatchment, the Q_a term doesn't have to be treated as a random variable and
443 event-specific information on the flow pathways may be inferred for a more precise account
444 of the hydrograph. But for the vast majority of rivers in the tropics, advances in remotely
445 sensed rainfall data are needed to achieve that situation and F_p may be all that is available to
446 inform public debates on the relation between forests and floods.

447 Figures 2 and 6 show that most of the effects of a decreasing F_p value on peak discharge
448 (which is the basis for downstream flooding) occur between F_p values of 1 and 0.7, with the
449 relative flood protection value reduced to 10% when F_p reaches 0.5. As indicated in Fig. 1,
450 peak discharge is only one of the factors contributing to flood risk in terms of human
451 casualties and physical damage. The F_p value has an inverse effect on the fraction of recent
452 rainfall that becomes river flow, but the effect on peak flows is less, as higher F_p values imply
453 higher base flow. The way these counteracting effects balance out depends on details of the
454 local rainfall pattern (including its Markov chain temporal autocorrelation), as well as the
455 downstream topography and risk of people being at the wrong time at a given place, but the F_p
456 value is an efficient way of summarizing complex land use mosaics and upstream topography
457 in its effect on river flow. The difference between wet-season and dry-season F_p deserves
458 further analysis. In climates with a real rainless dry-season, dry season F_p is dominated by the
459 groundwater release fraction of the watershed, regardless of land cover, while in wet season it
460 depends on the mix (weighted average) of flow pathways. The degree to which F_p can be
461 influenced by land cover needs to be assessed for each landscape and land cover combination,
462 including the locally relevant forest and forest derived land classes, with their effects on
463 interception, soil infiltration and time pattern of transpiration. The F_p value can summarize
464 results of models that explore land use change scenarios in local context. To select the
465 specific management actions that will maintain or increase F_p a locally calibrated land
466 use/hydrology model is needed, such as GenRiver or SWAT (Yen et al., 2015).

467 Although a higher F_p value will in most cases be desirable (and a decrease in F_p undesirable),
468 we may expect that downstream biota have adjusted to the pre-human flow conditions and its
469 inherent F_p and variability. Decreased variability of flow achieved by engineering
470 interventions (e.g. a reservoir with constant release of water to generate hydropower) may

471 have negative consequences for fish and other biota (Richter et al., 2003; McCluney et al,
472 2014).

473 **5.2 Credibility**

474 Key *credibility* questions are “Consistency of numerical results?” and “How sensitive are
475 results to bias and random error in data sources?”. This is further discussed in part II, after a
476 number of case studies has been studied. The main conclusions are that intra-annual
477 variability of F_p values between wet and dry seasons was around 0.2 in the case studies,
478 interannual variability in either annual or seasonal F_p was generally in the 0.1 range, while the
479 difference between observed and simulated flow data as basis for F_p calculations was mostly
480 less than 0.1. With current methods, it seems that effects of land cover change on flow
481 persistence that shift the F_p value by about 0.1 are the limit of what can be asserted from
482 empirical data (with shifts of that order in a single year a warning sign rather than a firmly
483 established change). When derived from observed river flow data F_p is suitable for monitoring
484 change (degradation, restoration) and can be a serious candidate for monitoring performance
485 in outcome-based ecosystem service management contracts. In interpreting changes in F_p as
486 caused by changes in the condition in the watershed, however, changes in specific properties
487 of the rainfall regime must be excluded. At the scale of paired catchment studies this
488 assumption may be reasonable, but in temporal change (or using specific events as starting
489 point for analysis), it is not easy to disentangle interacting effects (Ma et al., 2014). Recent
490 evidence that vegetation not only responds to, but also influences rainfall (arrow 10 in Figure
491 1; van Noordwijk et al., 2015b) further complicates the analysis across scales.

492 **5.3 Legitimacy**

493 *Legitimacy* aspects are “Does it match local knowledge?” and “Can it be used to empower
494 local stakeholders of watershed management?” and “Can it inform risk management?”. As the
495 F_p parameter captures the predictability of river flow that is a key aspect of degradation
496 according to local knowledge systems, its results are much easier to convey than full
497 hydrographs or exceedance probabilities of flood levels. By focusing on observable effects at
498 river level, rather than prescriptive recipes for land cover (“reforestation”), the F_p parameter
499 can be used to more effectively compare the combined effects of land cover change, changes
500 in the riparian wetlands and engineered water storage reservoirs, in their effect on flow
501 buffering. It is a candidate for shifting environmental service reward contracts from input to

502 outcome based monitoring (van Noordwijk et al., 2012). As such it can be used as part of a
503 negotiation support approach to natural resources management in which leveling off on
504 knowledge and joint fact finding in blame attribution are key steps to negotiated solutions that
505 are legitimate and seen to be so (van Noordwijk et al., 2013; Leimona et al., 2015).
506 Quantification of F_p can help assess tactical management options (Burt et al., 2014) as in a
507 recent suggestion to minimize negative downstream impacts of forestry operations on stream
508 flow by avoiding land clearing and planting operations in locally wet La Niña years. But the
509 most challenging aspect of the management of flood, as any other environmental risk, is that
510 the frequency of disasters is too low to intuitively influence human behavior where short-term
511 risk taking benefits are attractive. Wider social pressure is needed for investment in watershed
512 health (as a type of insurance premium) to be mainstreamed, as individuals waiting to see
513 evidence of necessity are too late to respond. In terms of flooding risk, actions to restore or
514 retain watershed health can be similarly justified as insurance premium. It remains to be seen
515 whether or not the transparency of the F_p metric and its intuitive appeal are sufficient to make
516 the case in public debate when opportunity costs of foregoing reductions in flow buffering by
517 profitable land use are to be compensated and shared (Burt et al., 2014).

518 **5.4 Conclusions and specific questions for a set of case studies**

519 In conclusion, the F_p metric appears to allow an efficient way of summarizing complex
520 landscape processes into a single parameter that reflects the effects of landscape management.
521 Flow persistence is the result of rainfall persistence and the temporal delay provided by the
522 pathway water takes through the soil and the river system. High flow persistence indicates a
523 reliable water supply, while minimizing peak flow events. Wider tests of the F_p metric as
524 boundary object in science-practice-policy boundary chains (Kirchoff et al 2015; Leimona et
525 al., 2015) are needed. Further tests for specific case studies can clarify how changes in tree
526 cover (deforestation, reforestation, agroforestation) in different contexts influence river flow
527 dynamics and F_p values. Sensitivity to specific realizations of underlying time-space rainfall
528 patterns needs to be quantified, before changes in F_p can be attributed to ‘watershed quality’,
529 rather than chance events.

530 **Data availability**

531 The algorithm used is freely available. Specific data used in the case studies are explained and
532 accounted for in Part II.

533 **Author contributions**

534 MvN designed method and paper, LT refined the empirical algorithm and handled the case
535 study data and modeling for part II, and BL contributed statistical analysis; all contributed and
536 approved the final manuscript

537 **Acknowledgements**

538 This research is part of the Forests, Trees and Agroforestry research program of the CGIAR.
539 Several colleagues contributed to the development and early tests of the F_p method. Thanks
540 are due to Eike Luedeling, Sonya Dewi, Sampurno Bruijnzeel and two anonymous reviewers
541 for comments on an earlier version of the manuscript.

758 **Abstract**

759 The way watersheds with their vegetation, soils, geomorphology and geological
760 substrate as well as riparian wetlands buffer the temporal pattern of riverflow relative
761 to the temporal pattern of rainfall is an important ecosystem service that requires
762 quantification. Part of it is inherent to its geology and climate, but another part is also
763 responding to human use and misuse of the landscape, and can be part of management
764 feedback loops if salient, credible and legitimate indicators can be found and used.
765 The benefits to humans of reduced exposure to floods and increased riverflow in
766 periods without rain are logically linked through the water balance. Dissecting the
767 anthropogenic change from exogenous variability (e.g. the specific time-space pattern
768 of rainfall during an observation period) is relevant for designing and monitoring of
769 watershed management interventions. Part I introduced the concept of flow
770 persistence, key to a parsimonious recursive model of river flow. It also discussed the
771 operational derivation of the F_p parameter. Here we compare F_p estimates from four
772 meso-scale watersheds in Indonesia (Cidanau, Way Besai, and Bialo) and Thailand
773 (Mae Chaem), with varying climate, geology and land cover history, at a decadal time
774 scale. The likely response in each of these four to variation in rainfall properties (incl.
775 the maximum hourly rainfall intensity) and land cover (comparing scenarios with
776 either more or less forest and tree cover than the current situation) was explored
777 through a basic daily waterbalance model, GenRiver. This model was calibrated for
778 each site on existing data, before being used to explore alternative land cover and
779 rainfall parameter settings. In both data and model runs, the wet-season (3-monthly) F_p
780 values were consistently lower than dry-season values for all four sites. Across the
781 four catchments F_p values decreased with increasing annual rainfall, but specific

782 aspects of watersheds, such as the riparian swamp (peat soils) in Cidanau reduced
783 effects of land use change in the upper watershed. Increasing the mean rainfall
784 intensity (at constant monthly totals for rainfall) around the values considered typical
785 for each landscape was predicted to decrease F_p values by between 0.047 (Bialo) and
786 0.261 (Mae Chaem). In three of the four watersheds the effects on F_p of shifts in mean
787 rainfall intensity were 2.2 to 3.1 times larger than the land use change scenarios, but in
788 Bialo its relative effect was only 58%. Apparently, the sensitivity to changes in land
789 use change plus changes in rainfall intensity depends on other characteristics of the
790 watersheds, and generalizations made on the basis of one or two case studies may not
791 hold, even within the same climatic zone. A wet-season F_p value above 0.7 was
792 achievable in forest-agroforestry mosaic case studies. Interannual variability in F_p was
793 found to be large relative to effects of land cover change. The sensitivity in the model
794 of Hortonian overland flow to variations in rainfall intensity can account for the
795 interannual variability. Multiple (5-10) years of paired-plot data would generally be
796 needed to reject no-change null-hypotheses on the effects of land use change
797 (degradation and restoration). While empirical evidence of such effects at scale is
798 understandably scarce, F_p trends over time serve as a holistic scale-dependent
799 performance indicator of degrading/recovering watershed health and can be tested for
800 acceptability and acceptance in a wider socio-ecological context.

801 **Introduction**

802 Inherent properties (geology, geomorphology) interact with climate and human modification
803 of vegetation, soils, drainage and riparian wetlands in the degree of buffering that watersheds
804 provide (Andréassian 2004; Bruijnzeel, 2004). Buffering of riverflow relative to the space-
805 time dynamics of rainfall is an ecosystem service, reducing the exposure of people living on
806 geomorphological floodplains to high-flow events, and increasing predictability and river
807 flow in dry periods (Joshi et al., 2004; Leimona et al., 2015; Part I). In the absence of any
808 vegetation and with a sealed surface, riverflow will directly respond to the spatial distribution
809 of rainfall, with only the travel time to any point of specific interest influencing the temporal
810 pattern of river flow. Any persistence or predictability of river flow in such a situation will
811 reflect temporal autocorrelation of rainfall, beyond statistical predictability in seasonal rainfall
812 patterns. On the other side of the spectrum, riverflow can be constant every day, beyond the
813 theoretical condition of constant rainfall, in a watershed that provides perfect buffering, by

814 passing all water through groundwater pools that have sufficient storage capacity at any time
815 during the year. Both infiltration-limited (Hortonian) and saturation-induced use of more
816 rapid flow pathways (inter and overland flows) will reduce the flow persistence and make it,
817 at least in part dependent on rainfall events. Separating the effects of land cover (land use),
818 engineering and rainfall on the actual flow patterns of rivers remains a considerable challenge
819 (Ma et al., 2014; Verbist et al., 2019). It requires data, models and concepts that can serve as
820 effective boundary object in communication with stakeholders (Leimona et al. 2015; van
821 Noordwijk et al. 2012). There is a long tradition in using forest cover as such a boundary
822 object, but there is only a small amount of evidence supporting this (Tan-Soo et al., 2014; van
823 Dijk et al., 2009; van Noordwijk et al. 2015a).

824 In part I, we introduced a flow persistence parameter (F_p) that links the two, asymmetrical
825 aspects of flow dynamics: translating rainfall excess into river flow, and gradually releasing
826 water stored in the landscape. Here, in part II we will apply the F_p algorithm to river flow
827 data for a number of contrasting meso-scale watersheds in Southeast Asia. These were
828 selected to represent variation in rainfall and land cover, and test the internal consistency of
829 results based on historical data: two located in the humid and one in the subhumid tropics of
830 Indonesia, and one in the unimodal subhumid tropics of northern Thailand.

831 After exploring the patterns of variation in F_p estimates derived from river flow records, we
832 will quantify the sensitivity of the F_p metric to variations in rainfall intensity, and its response,
833 on a longer timescale to land cover change. To do so, we will use a model that uses basic
834 water balance concepts: rainfall interception, infiltration, water use by vegetation, overland
835 flow, interflow and groundwater release, to a spatially structured watershed where travel time
836 from subwatersheds to any point of interest modifies the predicted riverflow. In the specific
837 model used land cover effects on soil conditions, interception and seasonal water use have
838 been included. After testing whether F_p values derived from model outputs match those based
839 on empirical data where these exist, we rely on the basic logic of the model to make inference
840 on the relative importance of modifying rainfall and land cover inputs. With the resulting
841 temporal variation in calculated F_p values, we consider time frame at which observed shifts in
842 F_p can be attributed to factors other than chance (that means: null-hypotheses of random
843 effects can be rejected with accepted chance of Type I errors).

844 **2. Methods**

845 **2.1 GenRiver model for effects of land cover on river flow**

846 The GenRiver model (van Noordwijk et al., 2011) is based on a simple water balance concept
847 with a daily timestep and a flexible spatial subdivision of a watershed that influences the
848 routing of water and employs spatially explicit rainfall. At patchlevel, vegetation influences
849 interception, retention for subsequent evaporation and delayed transfer to the soil surface, as
850 well as the seasonal demand for water. Vegetation (land cover) also influences soil porosity
851 and infiltration, modifying the inherent soil properties. Water in the root zone is modelled
852 separately for each land cover within a subcatchment, the groundwater stock is modelled at
853 subcatchment level. The spatial structure of a watershed and the routing of surface flows
854 influences the timedelays to any specified point of interest, which normally includes the
855 outflow of the catchment. Land-cover change scenarios are interpolated annually between
856 time-series (measured or modelled) data. The model may use measured rainfall data, or use a
857 rainfall generator that involves Markov chain temporal autocorrelation (rain persistence). As
858 our data sources are mostly restricted to daily rainfall measurements and the infiltration model
859 compares instantaneous rainfall to infiltration capacity, a stochastic rainfall intensity was
860 applied at subcatchment level, driven by the mean as parameter and a standard deviation for a
861 normal distribution (truncated at 3 standard deviations from the mean) proportional to it via a
862 coefficient of variation as parameter. For the Mae Chaem site in N Thailand data by Dairaku
863 et al. (2004) suggested a mean of less than 3 mm/hr. For the three sites in Indonesia we used
864 30 mm/hr, based on Kusumastuti et al. (2016). Appendix 1 provides further detail on the
865 GenRiver model. The model itself, a manual and application case studies are freely available
866 (<http://www.worldagroforestry.org/output/genriver-genetic-river-model-river-flow>;van
867 Noordwijk et al., 2011).

868 **2.2 Empirical data-sets, model calibration**

869 Table 1 and Fig.1 provides summary characteristics and the location of river flow data are
870 used in four meso-scale watersheds for testing the F_p algorithm and application of the
871 GenRiver model. Figure 1 includes a water tower category in the agro-ecological zones; this
872 is defined on the basis of a ratio of precipitation and potential evapotranspiration of more than
873 0.65, and a product of that ratio and relative elevation exceeding 0.277.

874 ⇒ Table 1

875 ⇒ Fig. 1

876 As major parameters for the GenRiver model were not independently measured for the
877 respective watersheds, we tuned (calibrated) the model by modifying parameters within a
878 predetermined plausible range, and used correspondence with measured hydrograph as test

879 criterion (Kobolt et al. 2008). We used the Nash-Sutcliff Efficiency (NSE) parameter (target
880 above 0.5) and bias (less than 25%) as test criteria and targets. Meeting these performance
881 targets (Moriassi et al., 2007), we accepted the adjusted models as basis for describing current
882 conditions and exploring model sensitivity. The main site-specific parameter values are listed
883 in Table 2 and (generic) land-cover specific default parameters in Table 3.

884 ⇒ Table 2

885 ⇒ Table 3

886 Table 4 describes the six scenarios of land-use change that were evaluated in terms of their
887 hydrological impacts. Further description on the associated land cover distribution for each
888 scenario in the four different watersheds is depicted in Appendix 2.

889 ⇒ Table 4

890 **2.3 Bootstrapping to estimate the minimum observation**

891 The bootstrap methods (Efron and Tibshirani, 1986) is a resampling methods that is
892 commonly used to generate ‘surrogate population‘ for the purpose of approximating the
893 sampling distribution of a statistic. In this study, the bootstrap approach was used to estimate
894 the minimum number of observation (or yearly data) required for a pair-wise comparison test
895 between two time-series of stream flow or discharge data (representing two scenarios of land
896 use distributions) to be distinguishable from a null-hypothesis of no effect. The pair-wise
897 comparison test used was Kolmogorov-Smirnov test that is commonly used to test the
898 distribution of discharge data (Zhang eta al, 2006). We built a simple macro in R (R Core
899 Team, 2015) that entails the following steps:

900 (i) Bootstrap or resample with replacement 1000 times from both time-series discharge
901 data with sample size n ;

902 (ii) Apply the Kolmogorov-Smirnov test to each of the 1000 generated pair-wise
903 discharge data, and record the P-value;

904 (iii) Perform (i) and (ii) for different size of n , ranging from 5 to 50.

905 (iv) Tabulate the p-value from the different sample size n , and determine the value of n
906 when the p-value reached equal to or less than 0.025 (or equal to the significance level
907 of 5%). The associated n represents the minimum number of observations required.

908 Appendix 3 provides an example of the macro in R used for this analysis.

909 **3. Results**

910 **3.1 Empirical data of flow persistence as basis for model parameterization**

911 Inter-annual variability of F_p estimates derived for the four catchments (Fig. 2) was of the
912 order of 0.1 units, while the intra-annual variability between dry and rainy seasons was 0.1-
913 0.2. For all for the years and locations, rainy season F_p values, with mixed flow pathways,
914 were consistently below dry-season values, dominated by groundwater flows. If we can
915 expect $F_{p,i}$ and $F_{p,o}$ (see equation 8 in part I) to be approximately 0.5 and 0, this difference
916 between wet and dry periods implies a 40% contribution of interflow in the wet season, a 20%
917 contribution of overland flow or any combination of the two effects.

918 Overall the estimates from modeled and observed data are related with 16% deviating more
919 than 0.1 and 3% more than 0.15 (Fig. 3). As the Moriasi et al. (2007) performance criteria for
920 the hydrographs were met by the calibrated models for each site, we tentatively accept the
921 model to be a basis for sensitivity study of F_p to modifications to land cover and/or rainfall

922 ⇒ Fig. 2

923 ⇒ Fig. 3

924 **3.2 Comparing F_p effects of rainfall intensity and land cover change**

925 A direct comparison of model sensitivity to changes in mean rainfall intensity and land use
926 change scenarios is provided in Fig. 4. Varying the mean rainfall intensity over a factor 7
927 shifted the F_p value by only 0.047 and 0.059 in the case of Bialo and Cidanau, respectively,
928 but by 0.128 in Way Besai and 0.261 in Mae Chaem (Fig. 4A). The impact of the land use
929 change scenarios on F_p was smallest in Cidanau (0.026), intermediate in Way Besai (0.048)
930 and relatively large in Bialo and Mae Chaem, at 0.080 and 0.084, respectively (Fig. 4B). The
931 order of F_p across the land use change scenarios was mostly consistent between the
932 watersheds, but the contrast between the ReFor and NatFor scenario was largest in Mae
933 Chaem and smallest in Way Besai. In Cidanau, Way Besai and Mae Chaem, variations in
934 rainfall were 2.2 to 3.1 times more effective than land use change in shifting F_p , in Bialo its
935 relative effect was only 58%. Apparently, the sensitivity to changes in land use change plus
936 changes in rainfall intensity depends on other characteristics of the watersheds, and
937 generalizations made on the basis of one or two case studies may not hold, even within the
938 same climatic zone.

939 ⇒ Fig. 4

940 **3.3 Further analysis of F_p effects for scenarios of land cover change**

941 Among the four watersheds there is consistency in that the 'forest' scenario has the highest,
942 and the 'degraded lands' the lowest F_p value (Fig. 5), but there are remarkable differences as
943 well: in Cidanau the interannual variation in F_p is clearly larger than land cover effects, while
944 in the Way Besai the spread in land use scenarios is larger than interannual variability. In
945 Cidanau a peat swamp between most of the catchment and measuring point buffers most of
946 landcover related variation in flow, but not the interannual variability. Considering the
947 frequency distributions of F_p values over a 20 year period, we see one watershed (Way Besai)
948 where the forest stands out from all others, and one (Bialo) where the degraded lands are
949 separate from the others. Given the degree of overlap of the frequency distributions, it is clear
950 that multiple years of empirical observations will be needed before a change can be affirmed.

951 Figure 4 shows the frequency distributions of expected effect sizes on F_p of a comparison of
952 any land cover with either forest or degraded lands. Table 5 translates this information to the
953 number of years that a paired plot (in the absence of measurement error) would have to be
954 maintained to reject a null-hypothesis of no effect, at $p=0.05$. As the frequency distributions
955 of F_p differences of paired catchments do not match a normal distribution, a Kolmorov-
956 Smirnov test can be used to assess the probability that a no-difference null hypothesis can
957 yield the difference found. By bootstrapping within the years where simulations supported by
958 observed rainfall data exist, we found for the Way Besai catchment, for example, that 20
959 years of data would be needed to assert (at $P = 0.05$) that the ReFor scenario differs from
960 AgFor, and 16 years that it differs from Actual and 11 years that it differs from Degrade. In
961 practice, that means that empirical evidence that survives statistical tests will not emerge,
962 even though effects on watershed health are real.

963 ⇒ Fig. 5

964 ⇒ Table 5

965 At process-level the increase in 'overland flow' in response to soil compaction due to land
966 cover change has a clear and statistically significant relationship with decreasing F_p values in
967 all catchments (Fig 6), but both year-to-year variation within a catchment and differences
968 between catchments influence the results as well, leading to considerable spread in the biplot.
969 Contrary to expectations, the disappearance of 'interflow' by soil compaction is not reflected
970 in measurable change in F_p value. The temporal difference between overland and interflow
971 (one or a few days) gets easily blurred in the river response that integrates over multiple
972 streams with variation in delivery times; the difference between overland- or interflow and
973 baseflow is much more pronounced. Apparently, according to our model, the high

974 macroporosity of forest soils that allows interflow and may be the 'sponge' effect attributed to
975 forest, delays delivery to rivers by one or a few days, with little effect on the flow volumes at
976 locations downstream where flow of multiple days accumulates. The difference between
977 overland- or interflow and baseflow in time-to-river of rainfall peaks is much more
978 pronounced..

979 ⇒ Fig. 6

980 Tree cover has two contradicting effects on baseflow: it reduces the surplus of rainfall over
981 evapotranspiration (annual water yield) by increased evapotranspiration (especially where
982 evergreen trees are involved), but it potentially increases soil macroporosity that supports
983 infiltration and interflow, with relatively little effect on waterholding capacity measured as
984 'field capacity' (after runoff and interflow have removed excess water). Fig. 7 shows that the
985 total volume of baseflow differs more between sites and their rainfall pattern than it varies
986 with tree cover. Between years total evapotranspiration and baseflow totals are positively
987 correlated (see supplementary information), but for a given rainfall there is a tradeoff. Overall
988 these results support the conclusion that generic effects of deforestation on decreased flow
989 persistence, and of (agro)/(re)-forestation on increased flow persistence are small relative to
990 interannual variability due to specific rainfall patterns, and that it will be hard for any
991 empirical data process to pick-up such effects, even if they are qualitatively aligned with valid
992 process-based models.

993 ⇒ Fig. 7

994 **4. Discussion**

995 In the discussion of Part I the credibility questions on replicability of the F_p metric and its
996 sensitivity to details of rainfall pattern versus land cover as potential causes of variation were
997 seen as requiring case studies in a range of contexts. Although the four case studies in
998 Southeast Asia presented here cannot be claimed to represent the global variation in
999 catchment behaviour (with absence of a snowpack and its dynamics as an obvious element of
1000 flow buffering not included), the diversity of responses among these four already point to
1001 challenges for any generic interpretation of the degree of flow persistence that can be
1002 achieved under natural forest cover, as well as its response to land cover change.

1003 The empirical data summarized here for (sub)humid tropical sites in Indonesia and Thailand
1004 show that values of F_p above 0.9 are scarce in the case studies provided, but values above 0.8
1005 were found, or inferred by the model, for forested landscapes. Agroforestry landscapes

1006 generally presented F_p values above 0.7, while open-field agriculture or degraded soils led to
1007 F_p values of 0.5 or lower. Due to differences in local context, it may not be feasible to relate
1008 typical F_p values to the overall condition of a watershed, but temporal change in F_p can
1009 indicate degradation or restoration if a location-specific reference can be found. The
1010 difference between wet and dry season F_p can be further explored in this context. The dry
1011 season F_p value primarily reflects the underlying geology, with potential modification by
1012 engineering and operating rules of reservoirs, the wet season F_p is generally lower due to
1013 partial shifts to overland and interflow pathways. Where further uncertainty is introduced by
1014 the use of modeled rather than measured river flow, the lack of fit of models similar to the
1015 ones we used here would mean that scenario results are indicative of directions of change
1016 rather than a precision tool for fine-tuning combinations of engineering and land cover change
1017 as part of integrated watershed management.

1018 The differences in relative response of the watersheds to changes in mean rainfall intensity
1019 and land cover change, suggest that generalizations derived from one or a few case studies are
1020 to be interpreted cautiously. If land cover change would influence details of the rainfall
1021 generation process (arrow 10 in Figure 1 of part I; e.g. through release of ice-nucleating
1022 bacteria Morris et al., 2014; van Noordwijk et al., 2015b) this can easily dominate over effects
1023 via interception, transpiration and soil changes.

1024 Our results indicate an intra-annual variability of F_p values between wet and dry seasons of
1025 around 0.2 in the case studies, while interannual variability in either annual or seasonal F_p was
1026 generally in the 0.1 range. The difference between observed and simulated flow data as basis
1027 for F_p calculations was mostly less than 0.1. With current methods, it seems that effects of
1028 land cover change on flow persistence that shift the F_p value by about 0.1 are the limit of what
1029 can be asserted from empirical data (with shifts of that order in a single year a warning sign
1030 rather than a firmly established change). When derived from observed river flow data F_p is
1031 suitable for monitoring change (degradation, restoration) and can be a serious candidate for
1032 monitoring performance in outcome-based ecosystem service management contracts.

1033 In view of our results the lack of robust evidence in the literature of effects of change in forest
1034 and tree cover on flood occurrence may not be a surprise; effects are subtle and most data sets
1035 contain considerable variability. Yet, such effects are consistent with current process and
1036 scaling knowledge of watersheds.

1037 **Data availability**

1038 Table 6 specifies the rainfall and river flow data we used for the four basins and specifies the
1039 links to detailed descriptions.

River Velocity	River flow velocity	m s ⁻¹	0.4	0.7	0.35	0.5

1121

1122 Table 3. GenRiver defaults for land-use specific parameter values, used for all four
 1123 watersheds (BD/BDref indicates the bulk density relative to that for an agricultural soil
 1124 pedotransfer function; see van Noordwijk et al., 2011)

1125

Land cover Type	Potential interception (mm/d)	Relative drought threshold	BD/BDref
Forest ¹	3.0 - 4.0	0.4 - 0.5	0.8 - 1.1
Agroforestry ²	2.0 - 3.0	0.5 - 0.6	0.95 - 1.05
Monoculture tree ³	1.0	0.55	1.08
Annual crops	1.0 - 3.0	0.6 - 0.7	1.1 - 1.5
Horticulture	1.0	0.7	1.07
Rice field ⁴	1.0 - 3.0	0.9	1.1 - 1.2
Settlement	0.05	0.01	1.3
Shrub and grass	2.0 - 3.0	0.6	1.0 - 1.07
Cleared land	1.0 - 1.5	0.3 - 0.4	1.1 - 1.2

1126 Note: 1. Forest: primary forest, secondary forest, swamp forest, evergreen forest, deciduous forest

1127 2. Agroforestry: mixed garden, coffee, cocoa, clove

1128 3. Monoculture : coffee

1129 4. Rice field: irrigation and rainfed

1130

1131 Table 4. Land use scenarios explored for four watersheds

Scenario	Description
NatFor	Full natural forest, hypothetical reference scenario
ReFor	Reforestation, replanting shrub, cleared land, grass land and some agricultural area with forest
AgFor	Agroforestry scenario, maintaining agroforestry areas and converting shrub, cleared land, grass land and some of agricultural area into agroforestry
Actual	Baseline scenario, based on the actual condition of land cover change during the modeled time period
Agric	Agriculture scenario, converting some of tree based plantations, cleared land, shrub and grass land into rice fields or dry land agriculture, while maintain existing forest
Degrading	No change in already degraded areas, while converting most of forest and agroforestry area into rice fields and dry land agriculture

1132

1133

1134 Table 5. Number of years of observations required to estimate flow persistence to reject the
 1135 null-hypothesis of ‘no land use effect’ at p-value = 0.05 using Kolmogorov-Smirnov test. The
 1136 probability of the test statistic in the first significant number is provided between brackets and
 1137 where the number of observations exceeds the time series available, results are given in *italics*

1190 Appendix 1. GenRiver model for effects of land cover on river flow

1191 The Generic Riverflow (GenRiver) model (van Noordwijk et al., 2011) is a simple
1192 hydrological model that simulates river flow based on water balance concept with a daily time
1193 step and a flexible spatial subdivision of a watershed that influences the routing of water. The
1194 core of the GenRiver model is a “patch” level representation of a daily water balance, driven
1195 by local rainfall and modified by the land cover and land-cover change and soil properties.
1196 The model starts accounting of rainfall or precipitation (P) and traces the subsequent flows
1197 and storage in the landscape that can lead to either evapotranspiration (E), river flow (Q) or
1198 change in storage (ΔS) (Figure App1):

1199 $P = Q + E + \Delta S$ [1]

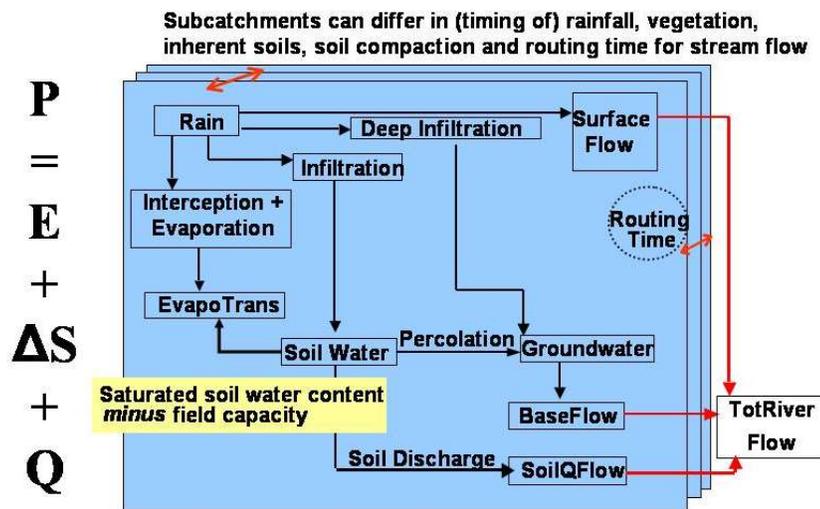

Figure App1. Overview of the GenRiver model

1200

1201 The model may use measured rainfall data, or use a rainfall generator that involves Markov
1202 chain temporal autocorrelation (rain persistence). The model can represent spatially explicit
1203 rainfall, with stochastic rainfall intensity (parameters RainIntensMean, RainIntensCoefVar in
1204 Table 2) and partial spatial correlation of daily rainfall between subcatchments. Canopy
1205 interception leads to direct evaporation of an amount of water controlled by the thickness of
1206 waterfilm on the leaf area that depends on the land cover, and a delay of water reaching the
1207 soil surface (parameter RainMaxIntDripDur in Table 2). The effect of evaporation of intercepted
1208 water on other components of evapotranspiration is controlled by the InterceptEffectontrans

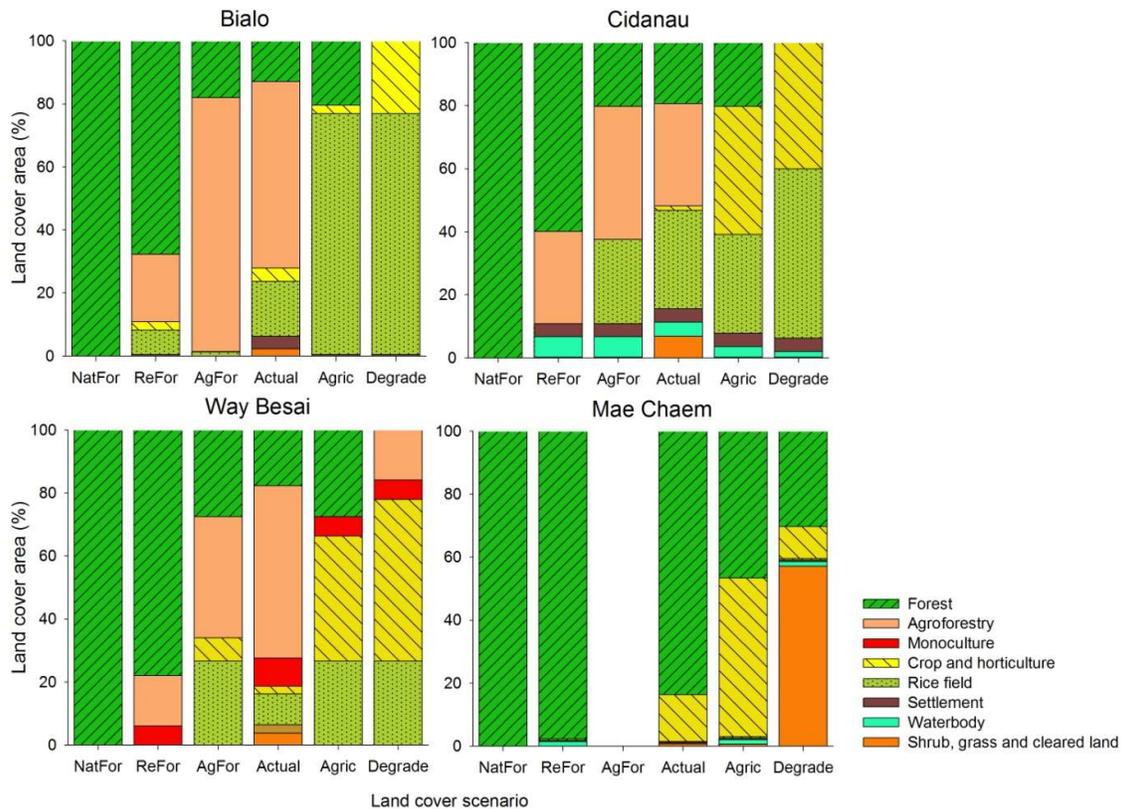

1209 parameter, that in practice may depend on the time of day rainfall occurs and local climatic conditions
1210 such as windspeed)

1211 At patchlevel, vegetation influences interception, retention for subsequent evaporation and
1212 delayed transfer to the soil surface, as well as the seasonal demand for water. Vegetation (land
1213 cover) also influences soil porosity and infiltration, modifying the inherent soil properties.
1214 Groundwater pool dynamics are represented at subcatchment rather than patch level,
1215 integrating over the landcover fractions within a subcatchment. The output of the model is
1216 river flow which is contribution from three types of stream flow: surface flow on the day of
1217 the rainfall event; interflow on the next day; and base flow as the slow flow. the multiple
1218 subcatchments that make up the catchment as a whole can differ in basic soil properties, land-
1219 cover fractions that affect interception, soil structure (infiltration rate) and seasonal pattern of
1220 water use by the vegetation. The subcatchment will also typically differ in “routing time” or
1221 in the time it takes the streams and river to reach any specified observation point (with default
1222 focus on the outflow from the catchment). The model itself (currently implemented in Stella
1223 plus Excel), a manual and application case studies are freely available
1224 (<http://www.worldagroforestry.org/output/genriver-genetic-river-model-river-flow> ;van
1225 Noordwijk et al., 2011).

1226

1227 Appendix 2. Watershed-specific consequences of the land use change scenarios

1228 The generically defined land use change scenarios (Table 4) led to different land cover
 1229 proportions, depending on the default land cover data for each watershed, as shown in Fig.
 1230 App2.

1231
 1232 Figure App2. Land use distribution of the various land use scenarios explored for the four
 1233 watersheds (see Table 4)

1234

1235 Appendix 3. Example of a macro in R to estimate number of observation required using
1236 bootstrap approach.

1237

```
1238 #The bootstrap procedure is to calculate the minimum sample size (number of observation) required
1239 #for a significant land use effect on Fp
1240 #bialo1 is a dataset contains delta Fp values for two different from Bialo watershed
1241
1242 #read data
1243 bialo1 <- read.table("bialo1.csv", header=TRUE, sep=",")
1244
1245 #name each parameter
1246 BL1 <- bialo1$ReFor
1247 BL5 <- bialo1$Degrade
1248
1249 N = 1000 #number replication
1250
1251 n <- c(5:50) #the various sample size
1252
1253 J <- 46 #the number of sample size being tested (~ number of actual year observed in the dataset)
1254
1255 P15= matrix(ncol=J, nrow=R) #variable for storing p-value
1256 P15Q3 <- numeric(J) #for storing p-Value at 97.5 quantile
1257
1258 for (j in 1:J) #estimating for different n
1259
1260 #bootstrap sampling
1261 {
1262 for (i in 1:N)
1263 {
1264 #sampling data
1265 S1=sample(BL1, n[j], replace = T)
1266 S5=sample(BL5, n[j], replace = T)
1267
1268 #Kolmogorov-Smirnov test for equal distribution and get the p-Value
1269 KS15 <- ks.test(S1, S5, alt = c("two.sided"), exact = F) P15[i,j] <- KS15$p.value
1270 }
1271
1272 #Confidence interval of CI
1273 P15Q3[j] <- quantile(P15[,j], 0.975)
1274
1275 }
1276
1277 #saving P value data and CI
1278
1279 write.table(P15, file = "pValue15.txt") write.table(P15Q3, file = "P15Q3.txt")v
```
