Dye tracing to determine flow properties of hydrocarbon-polluted Rabots glaciär, Kebnekaise, Sweden

Abstract

Over 11 000 L of kerosene was deposited on the surface of Rabots glaciär on the Kebnekaise Massif, northern Sweden, following the crash of a Royal Norwegian Air Force aircraft in March 2012. An environmental monitoring programme was subsequently commissioned, including a series of dye tracing experiments during the 2013 melt season, conducted to investigate the transport of pollutants through the glacier hydrological system. This experimental set-up provided a basis from which we could gain new insight to the internal hydrological system of Rabots glaciär. Results of dye tracing experiments reveal a degree of homogeneity in the topology of the drainage system throughout July and August, with an increase in efficiency as the season progresses, as reflected by decreasing temporary storage and dispersivity. Early onset of melting likely led to formation of an efficient, discrete drainage system early in the melt season, subject to decreasing sinuosity and braiding as the season progressed. Four distinct meltwater flow regimes are identified to summarize the temporal and spatial evolution of the system. Analysis of turbidity-discharge hysteresis further supports the formation of discrete, efficient drainage, with clockwise diurnal hysteresis suggesting easy mobilisation of readily-available sediments in channels. Dye injection immediately downstream of the pollution source zone reveals prolonged storage of dye followed by fast, efficient release. Twinned with a low dye recovery, and supported by sporadic detection of hydrocarbons in the proglacial river, we suggest that meltwater, and thus pollutants in solution, may be released periodically through an efficient, and likely pressurized hydrological system within the upper reaches of the glacier.

1 Introduction

Dye tracing provides an opportunity to study the otherwise unseen drainage system inside and underneath glaciers. Measuring the rapidity and pattern of dye emergence, as well the quantity of dye recovered at the proglacial outlet, can provide important insight into the form and efficiency of the glacier drainage system. Dye tracing has been applied successfully in the
alpine environment in several studies and has contributed substantially to understanding of
subglacial drainage systems, for example, Storglaciären in the Kebnekaise mountains in
northern Sweden (e.g. Seaberg et al., 1988; Hock and Hooke, 1993), glaciers in the European
Alps (e.g. Nienow et al., 1998), the High Artic (e.g. Bingham et al., 2005) and, more recently,
the Greenland Ice Sheet (Chandler et al., 2013; Cowton et al., 2013). More generally, the
number of extensive dye tracer studies of glaciers is still limited (Willis et al., 2012), and
basic unresolved issues remain in understanding the temporal and spatial variability of glacial
drainage systems, the extent of efficient drainage, and the morphology of englacial and
subglacial drainage.

The here considered Rabots glaciär in Kebnekaise mountains was subject to a large spill of
hydrocarbons, originating from a crash of a Royal Norwegian Air Force Lockheed Martin C-
130J Super Hercules aircraft on 15th March 2012. The aircraft crashed into the western face of
Kebnekaise, approximately 50 m below the mountain ridge, during a military exercise. Of the
initial 14100 L of kerosene jet fuel on board at take-off, an estimated minimum of 11100 L
was sprayed over the snow and ice-covered mountain environment, together with 50 L of
hydraulic oil and 170 L of turbo oil (Rosqvist et al., 2014). Some of the kerosene was
subsequently swept down and buried on Rabots glaciär by a large snow avalanche along with
the wreckage. Wreckage debris was also found on neighbouring Storglaciären and Björlings
glacier, but the majority was deposited on Rabots glaciär, which was not subject to immediate
clean-up or decontamination of fuel due to the hazardous nature of the impact site and the
large volume of snow affected.

Hydrocarbons were detected in the snow pack of the pollution source zone on Rabots glaciär
(Figure 1) and at sporadic intervals in the proglacial river system during the 2013 melt season
(Rosqvist et al., 2014). This provides evidence for active advection of pollutants through the
glacier system during 2013, the properties of which are discussed here following the
application of dye tracing. The transport of hydrocarbon pollution through a full glacier
system has never before been studied, and thus dye tracing is imperative if we are to
understand anything about advective travel times of pollutants in a glacier system.

Here, we present the results of dye tracing experiments conducted as part of a monitoring
programme on Rabots glaciär during the 2013 melt season, commissioned by the National
Property Board of Sweden (Statens Fastighetsverk). The main objectives are: (i) provide new
temporal and spatial information on the previously little-studied hydrological system of
Rabots glaciär, (ii) identity distinct meltwater flow regimes within the glacial hydrological
system based on analytically-derived properties of dye returns and (iii) to apply dye
breakthrough characteristics to evaluation of the transport of hydrocarbon pollution from the
source zone to the proglacial environment.

Rabots glaciär has received relatively little attention compared to neighbouring Storglaciären,
which is the best studied glacier in Sweden (e.g. Stenborg, 1965, 1969, 1973; Nilsson and
Sundblad, 1975; Schytt, 1981; Holmlund, 1988; Jansson, 1996; Schneider, 1999; Glasser et
al., 2003, Fountain et al., 2005), and an understanding of its hydrological system has been
extremely limited until now. The majority of dye tracing experiments in moulins on
Storglaciären have been conducted in the lower ablation zone below a riegel in the bedrock
topography (e.g. Seaberg et al., 1988; Hock and Hooke, 1993; Kohler, 1995), as the
overdeepened trough upstream of the riegel results in a largely englacial drainage system
(Hooke et al., 1988; Pohjola, 1994; Fountain et al., 2005) and an absence of surface meltwater
input points Dye tracing experiments conducted in crevasses, moulins or boreholes at
elevations above the riegel on Storglaciären have thus been limited and produced very
attenuated, or, in some cases, no dye return (Hooke et al., 1988; Jansson 1996). The greater
variability in subglacial topography beneath Storglaciären, compared to Rabots glaciär
(Björnsson, 1981) results in differences in surface to bed connections. On storglaciären input
points are highly localized to the riegel area, whereas on Rabots glaciär points are scattered
across a large portion of the glacier surface. For evaluating pollution transport through Rabots
glaciär it is thus clear that the knowledge from Storglaciären is not sufficient or even
applicable. The results presented below thus provide new insights into the hydrology of
Rabots glaciär with the aim of providing a basis for monitoring pollution transport. The study
also highlights the contrasts between the two glaciers and the effect of basal topography on
the hydrological system and system behaviour.

2 Site description

Rabots glaciär is a small, 3.1 km², polythermal valley glacier, situated on the western side of
Kebnekaise (2099 m a.s.l.) in sub-Arctic Sweden (Figure 1). The glacier extends from 1848 m
a.s.l. at its highest point down to 1111 m a.s.l. at the snout, with an average slope of 11.5°.
The maximum recorded Little Ice Age (LIA) extent of Rabots glaciär dates to 1910, as
captured in photographs taken in 1910 by Enqvist (Brugger and Pankratz, 2014). In
comparison to neighbouring Storglaciären, which has been characterised by a relatively stable
terminal position in the last c. 20 years, significant retreat of Rabots glaciär from its LIA
maximum and thinning continues due to its longer response time to climatic changes
(Brugger, 2007). Radio-echo sounding conducted in 1979 found that Rabots glaciär had a
maximum ice thickness of 175 m, with an average of 84 m (Björnsson, 1981). It also revealed
that the subglacial topography underneath Rabots glaciär is gently sloping with no
pronounced overdeepenings. This is in strong comparison to Storglaciären, for which the bed
is characterised by several subglacial overdeepenings and a pronounced bedrock riegel
(Björnsson, 1981). One may then expect Rabots glaciär to exhibit different hydrological
behaviour due to the less complex nature of topography beneath the glacier. Meltwater at the
terminus of Rabots glaciär leaves primarily through two proglacial streams. The high turbidity
of the northernmost of these streams indicates that it has much more interaction with bed
sediments than its relatively clear southern counterpart. The proglacial environment is
characterized by several braided systems that travel through an overridden inner moraine and
a pronounced terminal moraine (Karlén 1973). The overall hydrological catchment size
amounts to 9 km² with an ice covered area of 33%.

3 Methods

3.1 Meteorological data

Meteorological data were recorded between April and September 2013 by an automatic
weather station at 1355 m a.s.l. on Rabots glaciär. Meteorological variables, including air
temperature and precipitation, were measured every minute and the mean of these
measurements stored at 15 minute intervals. Air temperature was measured at 0.5, 1 and 2 m
above the surface using HygroClip T/Rh sensors and recorded as both transient and average
values. Total precipitation was recorded by a Young unheated tipping bucket rain gauge.

3.2 Proglacial river discharge

River gauging was conducted at a stable bedrock location in the proglacial river during the
2013 melt season, c. 1.5 km downstream of the glacier terminus (Figure 2). This location
permitted convergence of the proglacial outlets and measurement at an area of constrained
flow downstream of the numerous braided systems operating between terminal moraines.
Measurements of river stage and of air and water pressure were conducted between days 203
and 248 (Figure 3). Stage was measured by a SR50A sonic ranging sensor and pressure was recorded by HOBO U20 data loggers. Discharge time series were constructed from both relative gauging height (every 15 min) and relative water pressure (every 10 min) based on a rating curve produced by relating measured stage and pressure to discharge calculated for repeated rhodamine dye tracings (D1 to D5; Table 1) representative of varying water levels in the proglacial river.

3.3 Dye tracing experiments

Field campaigns targeting glacial hydrology were conducted during July and August 2013, during which 15 dye tracing experiments were carried out to quantify transit times and and flow properties of meltwater flow through crevasses in the upper reaches of the glacier, moulins throughout the ablation zone (Figure 2), and in the proglacial river (Table 1). Experiments were conducted across the altitudinal range of flowing surface meltwater on the glacier in order to understand how the englacial and subglacial hydrological system changes down-glacier. Dye injections in the pollution source zone alone provide only an average of englacial/subglacial conditions across the full altitudinal extent of the ablation zone. A known quantity of Rhodamine water tracer 20% solution (RWT) was used in the majority of dye tracer experiments, with Uranine (Na Fluorescein) 33.3% solution used when simultaneous experiments were desired. Uranine is susceptible to photo-degradation, so injection was conducted as close as safely possible to the englacial opening to reduce time exposed to sunlight. Dye was injected into flowing water in every case, upstream of open crevasses and moulins. Emergence of the dye was measured using both manual sampling and automated detection methods, and for all experiments, the sampling rates for both automatic and manual detection were less than 1/16 of the measured residence time (the time between dye injection and maximum detected concentration), as suggested by Nienow et al. (1996) to be the maximum acceptable period for accurate estimation of dispersivity.

For automated detection of dye emergence, an Albillia GGUN-FL30 field fluorometer was stationed in the proglacial stream (Figures 1 and 2), and was monitored at regular intervals to check the stability of the sonde within the stream. The FL30 is a flow-through fluorometer with a minimum detection limit of \(2 \times 10^{-11} \text{ g mL}^{-1}\), and allows detection of 3 separate tracers simultaneously, in addition to measuring turbidity and water temperature, at a
sampling rate up to 2 s. In order to establish the preferential flow pathway for meltwater originating at the hydrocarbon source zone, water samples were taken manually in both of the main streams emerging from the glacier front (Figures 1 and 2) during experiment A7. The samples were analysed for fluorescence with a Turner Designs AquaFluor handheld fluorometer, set up for Rhodamine WT at a minimum detection limit of 0.4 ppb. Based on calibration of the instruments (for a 100 ppb solution), fluorescence was converted to dye return concentration to produce breakthrough curves for each experiment. These dye returns were subsequently used to calculate the throughflow velocity, dispersion coefficient, dispersivity, storage retardation and dye recovery for each successful experiment (Table 2).

3.4 Dye breakthrough analysis

For each dye return a modelled concentration-time (breakthrough) curve was calculated using an advection-dispersion model (Brugman, unpublished; Seaberg et al., 1988; Cowton et al., 2013), at a temporal resolution of 30 s. The concentration of dye is represented as $c$ at time $t$, where $V_0$ represents the volume of injected dye, and $Q$ is discharge ($m^3 s^{-1}$), which was allowed to vary freely in order to produce a best fit to the measured breakthrough curve for each experiment (Willis et al., 1990; 2009). Variation of $Q$ was permitted even for the August experiments where $Q$ was measured, since discharge does not remain constant throughout an experiment, and to account for error associated with deriving discharge from a rating curve:

$$c(t) = \frac{v}{Q} \frac{V_0}{\sqrt{4\pi Dt}} \exp \left( -\frac{(x - vt)^2}{4Dt} \right) \quad (1)$$

Throughflow velocity, or transit speed, $v$ ($m s^{-1}$), for each experiment is calculated as:

$$v = \frac{x}{t_m} \quad (2)$$
where the transit distance \( x \) (m) is the straight line distance between the injection point and sampling location, and the residence time \( t_m \) (s) is the time between dye injection and peak concentration. This value was corrected for travel time in the stream during the August experiments to account for the different positioning of the FL30 fluorometer in July and August. The dispersion coefficient \( D \) (m\(^2\) s\(^{-1}\)) in equation (1) indicates the rate at which dye spreads within the glacier hydrological system (Willis et al., 2009). The variable \( t_j \) represents the time taken until half of the peak concentration on the rising \((t_j = t_1)\) and falling limb \((t_j = t_2)\) of the measured dye return curve. The equation is solved iteratively for \( t_m \) for both \( t_j = t_1 \) and \( t_j = t_2 \) until the equations converge to obtain the same value of \( D \) (Seaberg et al., 1988):

\[
D = \frac{x^2(t_m - t_j)^2}{4t_m^2t_j \ln\left(\frac{t_m}{t_j}\right)}
\]  

Dispersivity, \( d \) (m), is further calculated to describe the spreading rate of dye relative to the transit velocity through the glacier, providing an inference for transit route complexity (Seaberg et al., 1988; Willis et al., 1990):

\[
d = \frac{D}{v}
\]

Temporary storage of dye in the glacier results in elongation of the falling limb of the modelled return curve, and is not accounted for in the advection-dispersion model (Seaberg et al., 1988; Schuler et al., 2004; Willis et al., 2009). To examine this, storage retardation, \( SR \), is thus quantified as the percentage area difference under the measured and modelled falling limbs (Nienow 1993; Schuler 2002; Cowton et al. 2013). The higher the \( SR \), the lower the fit between the modelled and measured curve, thus the higher the temporary storage. Further, dye recovery, \( W \) (g), describes the weight of dye which passed through the fluorometer during an experiment, where \( dt \) is the logger interval in seconds, and \( Q \) is the average measured discharge for the duration of the experiment:
\[ W = \sum_{t=1}^{n} c Q dt \]  

(5)

The percentage dye recovery can then be expressed as a percentage, \( W\% \), where \( W_0 \) is the initial mass of the injected tracer:

\[ W\% = 100 \frac{W}{W_0} \]  

(6)

4 Results and interpretation

4.1 Proglacial discharge

Discharge in the proglacial river remains relatively small throughout the measurement period, with an average of 1.8 m\(^3\) s\(^{-1}\). In response to relatively high air temperatures in July (Figure 3), discharge reaches a maximum of 3.9 m\(^3\) s\(^{-1}\) on day 212, before experiencing a step-wise decrease to a period of steady discharge averaging around c. 1.3 m\(^3\) s\(^{-1}\) from day 221 to day 227. The second half of August is characterised by discharge fluctuating by c. 2 m\(^3\) s\(^{-1}\) in response to rainfall events and periods of higher air temperatures. Average discharge continues to fall into September. The diurnal cycle of discharge lags that of air temperature, with peak discharge occurring daily on average c. 2 h after peak recorded air temperature, representing the response time of the river to ablation and transit of meltwater through the glacier. The amplitude of the diurnal discharge cycle decreases throughout the melt season (Figure 3).

4.2 Turbidity

The turbidity of the proglacial river system, recorded in Nephelometric Turbidity Units (NTU), was not measured continuously throughout the season, but measured contemporaneously with dye fluorescence at the river gauging station (Figure 2) during 6 out
of 10 days in August 2013. Average peak discharge occurs within one hour of average peak turbidity (Figure 4C), indicating that mobilisation of sediments leads discharge. Hysteresis, a behaviour for which a value of the dependent variable can vary for a given value of the independent variable depending on whether the independent variable is increasing or decreasing (Hodgkins 1996), is observed both at the diurnal scale and at a multi-day scale, over a period of 10 days (Figure 4A and B). At the diurnal scale, hysteresis was observed only in a clockwise direction, while a figure-eight was produced at the multi-day scale, encompassing both clockwise and anticlockwise behaviour (Figure 4a, b). Clockwise hysteresis implies that peak diurnal turbidity leads peak diurnal discharge, as exemplified in Figure 4C, such that for equivalent discharge values on the rising and falling limbs of the hydrograph, turbidity is higher on the rising than the falling limb (Hodgkins, 1996). In this context, clockwise hysteresis can be interpreted as easy mobilisation of fresh sediment flushed out from channel beds and margins, followed by an exhaustion of sediment supply (Hodgkins, 1996; Singh et al., 2005; Pietron et al., in review). Given the short period of time over which turbidity was recorded at Rabots glaciär it is not possible to investigate multi-day evolution of sediment mobilisation over the melt season. However, within a limited period of 10 days we observe a figure-eight clockwise/anticlockwise hysteresis loop (Figure 4B). Conversely to clockwise behaviour, anticlockwise hysteresis implies that the peak in diurnal discharge leads the peak in diurnal turbidity, indicating that sediments are not as easily mobilised.

Diurnal observations of hysteresis in the proglacial river of Rabots glaciär were entirely clockwise, and are therefore comparable with the largely clockwise hysteresis recorded by Singh et al. (2005) for Gangotri Glacier in the Himalayas. Data collection in the Gangotri study, however, extended over a full melt season, much longer than our 10 day, non-continuous measurement period. One may compare further with observations of hysteresis at Scott Turnerbreen in Svalbard (Hodgkins, 1996), for which a progressive change in hysteresis from clockwise to anticlockwise was observed during the melt season. Scott Turnerbreen is a ‘cold-based’, non-temperate glacier (Hodgkins, 1996), while Rabots glaciär is polythermal, and because of differences in the glacier hydrological system, particularly at the bed, this may explain why we do not see anticlockwise diurnal hysteresis in the late melt season at Rabots glaciär. Temperate Bench glacier in Alaska has also been observed to produce clockwise behaviour, including during two flood events (Riihimaki et al., 2005). The anticlockwise pattern observed between days 220 and 222 (Figure 4B) follows a period of increased
temperatures between days 217 to 219 (Figure 3). Sediments within the glacier system may have been flushed out, and sourced from higher elevation, during this period due to higher melt rates, followed by a period of sediment exhaustion. This may have been exacerbated by the prevalence of silty sediments subject to strong cohesion in the glacier forefield, reducing the possibility for sediment mobilisation. The sharp increase in turbidity in the Rabots glaciär proglacial stream during day 228 is likely a reflection of a peak in temperature, combined with a precipitation event, lagged by a peak in discharge (Figure 3). We hypothesise that increased temperature, and thus increased meltwater availability, combined with a precipitation event (Figure 3), may have permitted extension of the network of subglacial conduits during this period, allowing access to a fresh sediment supply at the glacier bed, as also observed by Riihimaki et al. (2005).

4.3 Dye breakthrough

Results from calculation of analytical dye return parameters for each experiment are listed in Table 2, along with discharge calculated for each experiment based on measurements in the proglacial river. Measured breakthrough curves are illustrated for each successful glacier dye tracing experiment in Figure 5. Experiments A5 and A6 were unsuccessful due to failure of the fluorometer data logger. Modelled breakthrough curves and dye recovery are also depicted for the August experiments. Visual interpretations of the breakthrough curves reveal that there is a decrease in curve width with progression of the season, as well as an increase in symmetry. All curves except J1 and J2 exhibit a smooth asymmetric form, as observed elsewhere (e.g. Seaberg et al., 1988, Willis et al., 1990; Cowton et al., 2013), and are characterised by clear single peak breakthrough curves. Breakthrough curves J1 and J2 are more complex in form, with longer falling limbs that do not reach base level values before the end of the experiments. These curves are also characterised by a higher degree of noise, likely due to low dye recovery. Breakthrough curves characterised by rapid dye return, with a narrow, single-peaked form are interpreted to be indicative of an efficient sub-/englacial drainage system (Hubbard and Nienow, 1997). This interpretation can be further strengthened by values of low dispersivity and storage, and fast throughflow velocities, indicative of high throughput of water in a channelized system (e.g. Cowton et al., 2013).

Experiment A7 was monitored simultaneously by both automated fluorescence detection and manual water sampling in both major proglacial outlets. The dye emerged only in the
southernmost, less turbid proglacial outlet. The dye breakthrough curve derived from the analysis of water from manual sampling was in accordance with that from automated detection using the FL30 both in terms of form and emergence time. That manually-analysed breakthrough curve was, however, characterised by increased noise due to turbidity, which is not corrected for in manual sampling. The breakthrough curves of experiment A7 represent meltwater flow from as close to the source zone as was possible with the condition of flowing water for injection. Both curves reached their peak c. 14 hours after injection, after c. 12 hours with no dye signal. The residence time, form of the breakthrough curve, and emergence of the dye in only one (less turbid) proglacial outlet indicates temporary storage followed by a rapid release of meltwater, with little interaction with the bed substrate.

4.4 Throughflow velocities

Calculated throughflow velocities are an average of flow velocities within the englacial and subglacial drainage system between the injection site and detection point. Throughflow velocities range from 0.04 to 0.28 m s\(^{-1}\) for the glacier-based experiments (Table 2), which fall within the range of values previously inferred from experiments on Storglaciären (Seaberg et al., 1988; Hock and Hooke, 1993). A threshold of 0.2 m s\(^{-1}\) is proposed by Theakstone and Knudsen (1981) and Nienow (2011) to distinguish between fast and slow flow. Willis et al. (2009) propose a similar threshold for fast flow, considering velocities of <0.05 m s\(^{-1}\) as slow, c. 0.1 m s\(^{-1}\) as moderate and >0.15 m s\(^{-1}\) as fast. Flow velocities above the proposed thresholds for fast flow have traditionally been interpreted as indicative of channelised transport while flow velocities below the threshold indicate distributed water routing (Seaberg et al. 1988; Willis et al. 1990; Cowton et al. 2013). Throughflow velocities in Rabots glaciär’s proglacial river reached a maximum of 0.58 m s\(^{-1}\). We observed no clear relationship between velocity and elevation of dye injections on the glacier, or between velocity and time into the season. The lowest values of throughflow velocity were calculated for experiment A7, and we hypothesise that they are representative of a relatively long period of initial storage before more rapid flow following a sudden meltwater release.

Following Leopold and Maddock (1954), the relationship between throughflow velocity and discharge can be expressed as a simple power function. There is a positive correlation between throughflow and discharge both for glacier-based dye returns (\(R^2 = 0.65\) and
proglacial returns \( R^2 = 0.27 \) at Rabots glaciär (Figure 6). The results of this study are compared against those from neighbouring polythermal Storglaciären (Seaberg et al., 1988) and temperate outlet glacier Midtdalsbreen, Norway (Willis et al., 1990) in Table 3. Seaberg et al. (1988) differentiated between proglacial and sub/englacial flow, while Willis et al. (1990) divided recorded discharge two tributary systems T1 and T3, which were interpreted as draining two different glacial hydrological systems. In the proglacial system of Rabots glaciär, velocity increases with the 0.6 power of the discharge. The associated multiplier is lower than that calculated for Sydjokk, one of the proglacial rivers of neighbouring Storglaciären (Seaberg et al., 1988), such that velocity through Sydjokk is 2.8 times larger than for the Rabots glaciär proglacial river. The braided nature of the Rabots proglacial river as it navigates through the proglacial outwash plain and terminal moraines may explain this difference.

The exponent of the en- and subglacial drainage is also significantly higher in this study compared with Storglaciären and Midtdalsbreen, while the multiplier is in the same order as that for Midtdalsbreen. For a given discharge, the velocity of water flowing en- or subglacially or both in Rabots glaciär is thus 2-3 times lower than Midtdalsbreen, and 13 times lower than Storglaciären. The much larger exponent for en-/subglacial flow through Rabots glaciär may indicate that discharge is accommodated by an increase in hydraulic gradient within the system due to backing up of water, and by decreasing sinuosity, as proposed both for Storglaciären (Seaberg et al., 1988) and T1 of Midtdalsbreen (Willis et al., 1990), rather than through changes in cross-sectional channel area. Cowton et al. (2013) and Nienow et al. (1998) state that a flow in a channelised system is expected to be 1-2 orders of magnitude higher than in a distributed system. We do not see this order of magnitude difference in our data (Table 2), or an increase in velocity over time, which is likely a product of early onset melt and development of the drainage system.

### 4.5 Dispersivity

Low dispersivities (< 5 m) are typically indicative of efficient water routing, and high values of dispersivity (> 20 m) have been associated with drainage of decreased efficiency, possibly due to distributed drainage system form (Nienow et al. 1998; Bingham et al. 2005; Willis et al. 2009). Water that is stored either supraglacially or englacially may also increase the rate of dispersivity (Fountain 1993; Schuler et al. 2004); for example through buffering of meltwater...
flow in snow and firn layers, or storage in englacial fracture networks. From visual interpretation of the return curves (Figure 5) the elongation of the falling limb in relation to the rising limb decreases with time into the melt season. This is supported by falling values of both dispersivity and the dispersion coefficient (Table 2), with the exception of experiment A7, for which dispersivity experiences a fourfold increase compared to experiment A4. A7 was the highest elevation at which dye was injected, which likely explains the increase in dispersivity despite being late in the melt season (Figure 7B). We interpret the decrease in dispersivity over time (Table 2) as an increase in drainage system efficiency, despite a general decrease in discharge and its diurnal cyclicity after peak discharge in late July (Figure 3). We find no significant relationship between dispersivity and either velocity or elevation (Figure 7A, B), with R² values of 0.19 and 0.35 respectively. We do, however, find a positive relationship between dispersivity and storage retardation (Figure 7C), with an R² value of 0.85, relating the spreading rate of dye to the temporary storage of dye in the system.

5 Discussion

5.1 Meltwater flow regimes

We propose that clustering of the values of the variables throughflow velocity, storage retardation, elevation, discharge, and dispersivity (Figure 6, Figure 7), in concert with breakthrough curve form (Figure 5), indicates the existence of four distinct meltwater flow regimes, as summarized in Figure 8. Regime 1 encompasses experiments J1 and J2, which are characterised by both high dispersivity, relatively high throughflow velocities despite occurring earliest in the field season, high storage retardation and are representative of relatively low drainage system efficiency. The velocity values may imply channelized but sinuous flow, possibly impeded by interaction with basal sediments down the relatively long flow pathways, resulting in noisy, multi-peaked breakthrough curves (Figure 5). Regime 2 is represented solely by experiment J3, which depicts a large decrease in dispersivity and an increase in system efficiency, seventeen days after experiment J2. The breakthrough curve for J3 is single-peaked, but the elongated falling limb illustrates temporary storage of dye, albeit less than for regime 1. The northernmost stream through which the July experiments likely exited the glacier is very turbid. Interaction with basal sediments may contribute to the high storage retardation characteristic of regimes 1 and 2.
Regime 3 contains experiments A1, A2 and A4, which are the three lowest elevation experiments, characterised by low dispersivity, low storage retardation and high throughflow velocities (Figure 7, Figure 8). Flow through these moulins has the shortest travel pathway through the system, with dye injected at relatively low elevation, late into the ablation season, into a system relatively high in discharge. Breakthrough curves in regime 3 are all single peaked and very narrow (Figure 5), which combined with the characteristics summarized in Figure 8, indicate a high degree of drainage system efficiency. Experiments A3 and A7 fall under flow regime 4, characterised by low throughflow velocities, low storage retardation, low dispersivity and relatively low discharge. The form of the breakthrough curves for A3 and A7 is single-peaked but, which supports channelized flow, despite low throughflow velocities. Injection point A3 is located just up-glacier of moulins used for experiments A1, A2 and A4 (regime 3). Despite this, there is a considerable increase in residence time for experiment A3; at least 2.5 hours longer than for experiments within regime 3. The residence time of A7 is the longest of the successful experiments, at c. 14 hours, characterised by a broad yet single-peaked breakthrough curve (Figure 5).

When comparing selected attribute pairs for experiments A3 and A7 (Figure 8), the only variable for which clustering is not produced is elevation, suggesting a long operating pathway between these two injection points (Figure 2). We interpret the behaviour depicted by the breakthrough curve of experiment A7 as reflecting sub/englacial meltwater storage followed by periodic release through an efficient system, addressing contemporaneous long residence time, low throughflow velocities, low dye recovery, yet a single-peaked dye breakthrough curve with low storage retardation. Only six days past between the experiments in regime 3 and experiment 7, and experiment A3 was conducted on the same afternoon as experiment A4 in regime 3, thus the distinction between these two regimes is spatial, and not temporal. Analysis of throughflow velocities against discharge (Figure 6, Table 3) indicated that backing up of water may occur within the hydrological system of Rabots glaciär to accommodate discharge within a system decreasing in sinuosity with distance downstream, resulting in an increased hydraulic gradient with elevation. We may then expect that a pressurized system still existed late into the season at the locations of experiments in regime 4, resulting in the observed low throughflow velocities (Figure 8), while dye injections within regime 3 entered a low pressure system with fast meltwater flow.
5.2 Meltwater storage

The temporary storage of dye can be viewed as an influencing factor on dispersion (Figure 7e), which manifests itself as an elongation in the falling limb of modelled breakthrough curves (Figure 5; Willis et al., 2009; Cowton et al., 2013). With the exception of experiment A7, we observe a 60% reduction in storage retardation in glacier-based dye tracer tests over time (Table 2). The largest storage values correspond with the more complex breakthrough curves from the July experiments, relating to high dispersivity and a less efficient drainage system. As throughflow velocities showed no increase with time, we propose that the reduction in storage retardation over time relates to increasing efficiency, and decreasing sinuosity, rather than evolution from a true distributed system to a channelized system, which had likely already formed due to early onset of melting in 2013. Similar behaviour was reported by Cowton et al. (2013) for the Leverett Glacier, southwest Greenland. Low dye recovery was calculated for experiments A2 and A4. Uranine was used as a tracer in these experiments, thus low dye recovery is likely accounted for by photochemical decay of the dye between emergence from the glacier terminus and detection by the fluorometer downstream.

Combined with a very low dye recovery (Table 2), the mechanism of storage and release proposed to explain the return curve of experiment A7 may be indicative of storage in the englacial system (Fountain, 1993; Cowton et al., 2013). In this case, quantities of the injected dye, which become dilute as more meltwater enters the system, may be released periodically under pressure, resulting in a low dye recovery and a broad, single-peaked breakthrough curve. This hypothesis is strengthened by the 5% storage retardation calculated for automated sampling during the experiment (Table 2). Sporadic detection of hydrocarbons in the proglacial system (Rosqvist et al., 2014), rather than continuous emergence of pollutants, further attests to periodic release of meltwater and pollutants stored within the en-/subglacial hydrological system. The stream in which dye emergence from experiment A7 was detected manually has a very low turbidity in comparison to its northern counterpart, which allows us to further hypothesize that meltwater emerging in the southern proglacial outlet interacts with the bed to a lesser degree, and is possibly routed downstream for a long distance within the englacial system. Low recovery rates for both manual and automated sampling of experiment A7 may be exacerbated by refreezing of dye onto the ice since dye detection continued overnight, during falling temperatures and very low discharge.
With the exception of experiment D1, proglacial dye experiments for production of a rating curve resulted in recovery of at least 78% of the dye, with sorption to sediment particles likely to contribute to this result. Storage retardation varied between 18% and 38%, and for three of these experiments storage retardation exceeded the percentage of dye that was not recovered. This overestimation of storage retardation may partly be attributed to the advection-dispersion model, which was adjusted for best fit to the measured breakthrough curve, and for which only the falling limb is considered when computing storage retardation. The presence of dye from previous experiments within the braided proglacial system, mobilised in periods of increased water level and discharge, may also affect recovery of dye, as could fluorescence from suspended sediments at the same wavelength as Rhodamine WT (Cowton et al., 2012).

5.3 Implications for transport of pollutants

Kerosene fractions that remain in the initial source zone (Figure 1) after surface volatilization (Jarsjö et al., 1994) can potentially dissolve into and move with meltwater through Rabots glaciär. Extensive plumes of dissolved contaminants often develop down-gradient of hydrocarbon source zones due to advection, as for instance shown through monitoring of numerous spills in industrial areas (e.g., Jarsjö et al., 2005). The distribution of advective travel times derived from tracer experiments provides an essential basis in quantifying governing transport and attenuation-retention processes for kerosene dissolved in meltwater, which previously have been shown for large-scale spreading of dissolved contaminants in non-glaciated environments (Darracq et al., 2010; Destouni et al., 2010).

In this context, current results provide a first quantification of the large difference in transport conditions between the hydrocarbon-polluted Rabots glaciär and well-documented cases of hydrocarbon pollution in groundwater near industrial areas; most notably, the throughflow velocities (0.04 to 0.28 m s⁻¹) of Rabots glaciär are at least two orders of magnitude higher than typical advective travel times in contaminated sand aquifers of Europe (Jarsjö et al., 2005). Whereas this means risk for rapid spreading to downstream waters, the here shown existence of flow regimes characterized by relatively low tracer recovery and high storage retardation also implies that part of the dissolved kerosene may be retained in Rabots glaciär for extended periods of time. In addition, surplus kerosene from the initial source zone may potentially move with water in free (non-dissolved) phase into the drainage system of the
glacier; for instance, relatively light hydrocarbon mixtures like kerosene will float on top of water-saturated zones (e.g., Schwille, 1981).

5 Conclusions

The results of dye tracing experiments provide a first look into the internal hydrological system of Rabots glaciär, offering a new insight into both the properties and transit times of meltwater flow through the glacier. In response to an early start to the melt season, development of efficient drainage began in July, with return curves supporting increased efficiency and decreasing sinuosity throughout August. Analysis of proglacial discharge and turbidity attests further to formation of efficient subglacial drainage, with clockwise hysteresis supporting easy mobilisation of sediments readily available within channels, thus also any pollutants that may have sorbed onto sediments. More extensive dye tracing studies are necessary to explore the full seasonal evolution of the Rabots glaciär hydrological system. Nevertheless, this study provides a first insight to the drainage system topology, which should be explored further in future studies in concert with an investigation of the internal thermal structure of the glacier. Although limited in number, the results of these experiments suggest that in comparison to Storglaciären, the internal hydrological system of Rabots glaciär is characterised by a degree of homogeny in efficiency over a larger altitudinal extent, although constrained and divided laterally by the ice flow and structure of the glacier.

Assuming flow of pollutants in solution with meltwater, the delayed but efficient form of breakthrough curve A7, combined with a very low dye return, indicates that pollutants are being periodically released from an en-/subglacial store after entering the internal glacier hydrological system near the source zone. This is supported by sporadic rather than continuous detection of hydrocarbons in the proglacial river system. Experiment A7, originating directly downstream of the source zone, estimates a transit time of c.15 hours for transport through the full en-/subglacial hydrological system. By mid-August, the drainage system is well-developed, producing efficient breakthrough of dye, even for experiment A7 which originated above 1350 m a.s.l. and a very short distance from the remaining snowpack. Snow is highly permeable and thus unlikely to retain pollutants at the multi-year scale, but pollutants stored within the firn layer and ice mass will continue to be released gradually by ablation processes during future melt seasons. Storage within firn and ice, and within the internal hydrological system as demonstrated here, provides an opportunity for refreezing, further increasing the permanence of pollutants in the glacier system. The results presented
here offer an important insight to the transport of pollutants through a full glacier system contributing towards a broader analysis of the spread, longevity and impact of hydrocarbon pollutants in the Rabots glaciär hydrological catchment.

**Author contribution**

C. C. Clason led and all other authors contributed to the writing of the manuscript. Fieldwork was conducted by all authors, C. C. Clason designed the glacier hydrological experiments, C. Coch and C. C. Clason analysed the data and prepared figures.

**Acknowledgements**

This work was funded in 2012 by Formas (grant number BR9912A to G. Rosqvist) and Statens Fastighetsverk. We wish to thank Torbjörn Karlin, Susanne Ingvander, Ane LaBianca, Andrew Mercer, Pia Eriksson and Victor Plevrakis for their help in instrumentation set-up and data collection in the field, and Per Holmlund for providing imagery. We also wish to thank Christian Helanow, Mauri Pelto and two anonymous reviewers for their comments which helped to improve the manuscript. K. Brugger gratefully acknowledges financial support from the University of Minnesota, Morris' Faculty Research Enhancement Funds.
