Abstract

Soil moisture dynamics reflect the complex interactions of meteorological conditions with soil, vegetation and terrain properties. In this study, intermediate scale soil moisture estimates from the cosmic-ray neutron sensing (CRNS) method are evaluated for two semiarid ecosystems in the southwestern United States: a mesquite savanna at the Santa Rita Experimental Range (SRER) and a mixed shrubland at the Jornada Experimental Range (JER).

Evaluations of the CRNS method are performed for small watersheds instrumented with a distributed sensor network consisting of soil moisture sensor profiles, an eddy covariance tower and runoff flumes used to close the water balance. We found an excellent agreement between the CRNS method and the distributed sensor network (RMSE of 0.009 and 0.013 m³/m³ at SRER and JER) at the hourly time scale over the 19-month study period, primarily due to the inclusion of 5 cm observations of shallow soil moisture. Good agreement was also obtained in soil moisture changes estimated from the CRNS and watershed water balance methods (RMSE = 0.001 and 0.038082 m³/m³ at SRER and JER), with deviations due to bypassing of the CRNS measurement depth during large rainfall events. This limitation, however, was once validated, the CRNS soil moisture estimates were used to investigate hydrological processes at the footprint scale at each site. Through the computation of the water balance, we showed that drier-than-average conditions at SRER promoted plant water uptake from deeper soil layers, while the wetter-than-average period at JER resulted in leakage towards deeper soils. Using the distributed sensor network, we quantified the spatial variability of soil moisture in the CRS footprint and the relation. The CRNS measurements were then used to quantify the link between evapotranspiration and soil moisture, in both cases at
a commensurate scale, finding similar predictive relations at both sites that are applicable to other semiarid ecosystems in the southwestern U.S. Furthermore, soil moisture spatial variability was related to evapotranspiration in a manner consistent with analytical relations derived using the CRS method, opening up new possibilities for understanding land-atmosphere interactions.

Keywords: watershed hydrology, soil moisture variability, evapotranspiration, land-atmosphere interactions, COSMOS, North American monsoon.
1. Introduction

Soil moisture is a key land surface variable that governs important processes such as the rainfall-runoff transformation, the partitioning of latent and sensible heat fluxes and the spatial distribution of vegetation in semiarid regions (e.g., Entekhabi, 1995; Eltahir, 1998; Vivoni, 2012). Semiarid watersheds with heterogeneous vegetation in the southwestern United States (Gibbens and Beck, 1987; Browning et al., 2014) exhibit variations in soil moisture that challenge our ability to quantify land-atmosphere interactions and their role in hydrological processes (Dugas et al., 1996; Small and Kurc, 2003; Scott et al., 2006; Gutiérrez-Jurado et al., 2013; Pierini et al., 2014). Moreover, accurate measurements of soil moisture over scales relevant to land-atmosphere interactions in watersheds are difficult to obtain. Traditionally, soil moisture is measured continuously at single locations using techniques such as time domain reflectometry and then aggregated in space using a number of methods (Topp et al., 1980; Western et al., 2002; Vivoni et al., 2008b). Soil moisture is also estimated using satellite-based techniques, such as passive or active microwave sensors, but spatial resolutions are typically coarse and overpass times infrequent (e.g., Kustas et al., 1998; Moran et al., 2000; Kerr et al., 2001; Bartalis et al., 2007; Narayan and Lakshmi, 2008); Entekhabi et al., 2010), but spatial resolutions are typically coarse and overpass times infrequent as compared to the spatiotemporal variability of soil moisture occurring within semiarid watersheds.

One approach to address the scale gap in soil moisture estimation is through the use of cosmic-ray neutron sensing (CRS) measurements (Zreda et al., 2008, 2012) that provide soil moisture with a measurement footprint of several hectares (Desilets et al., 2010). Developments of the CRS method have focused on understanding the processes affecting the measurement technique, for example, the effects of vegetation growth (Franz et al., 2013a;
Coopersmith et al., 2014), atmospheric water vapor (Rosolem et al., 2013), soil wetting and
drying (Franz et al., 2012a), and horizontal heterogeneity (Franz et al., 2013b). To date, the
validation of the CRS method CRNS technique has been performed using single site
measurements, spatial aggregations of different measurement locations, and particle transport
models (Desilets et al., 2010; Franz et al., 2013b; Zhu et al., 2015). Distributed sensor
networks measuring the water balance components of small watersheds and the spatial variability
of soil moisture within a watershed scale, however, offer the CRNS opportunity to test the accuracy
of the CRNS method through multiple, independent approaches. For instance, the CRNS
technique can also be validated based upon the application of the watershed water balance
equation, as performed for the eddy covariance (EC) technique often used to measure surface
turbulent fluxes (Scott, 2010; Templeton et al., 2014). In small watersheds of comparable size to
the CRS measurement footprint, the water balance Once validated, CRNS soil moisture estimates
can be expressed as:

\[
\frac{\Delta \theta}{\Delta t} = \frac{P - ET - Q - L}{z_m},
\]

(1)

where \( \theta \) is volumetric soil moisture, \( P \) is precipitation, \( ET \) is evapotranspiration, \( Q \) is streamflow;
and \( L \) is leakage, used to apply the water balance equation in a continuous fashion with all of the
terms expressed as spatially-averaged quantities the aim of quantifying hydrological fluxes during
storm and valid over the effective soil measurement depth \( (z_m) \). Closing the water balance, or the
estimation of each term of (1), would be a novel way for comparing interstorm periods, including
the CRS method to independent observations valid at a commensurate spatial and temporal scale.
Nevertheless, the application occurrence of (1) can be fraught with issues related to
measurement limitations and representativeness deeper soil layers or when spatially-averaged
quantities are difficult to obtain in heterogeneous watersheds.

Soil moisture measurements at the intermediate scales provided by the CRS method do not capture the spatial variability within the measurement footprint (Zreda et al., 2008). As a result, distributed sensor networks consisting of different locations in a watershed are essential for establishing how the spatially-averaged properties are obtained (e.g., Franz et al., 2012b). Capturing the soil moisture spatial variability within a measurement footprint is also important for improving the representation of land-atmosphere interactions and hydrologic processes in models (Famiglietti and Wood, 1994; Bindlish et al., 2009; Mascaro and Vivoni, 2012). Based on prior studies the CRNS technique is that its measurement scale is comparable to the footprint of evapotranspiration (ET) measurements based on the EC technique, whose extent depends on wind speed and direction, atmospheric stability, and instrument and surface roughness heights (e.g., Hsieh et al., 2000; Kormann and Meixner, 2001; Falge et al., 2002). Furthermore, the relation between ET and soil moisture is an important parameterization in land surface models (e.g., Laio et al., 2001; Rodríguez-Iturbe and Porporato, 2004; Vivoni et al., 2008a) and, in most cases, has been investigated using distributed sensor networks, the spatial variability of soil moisture is expected to increase with wetter spatially-averaged conditions in the range of values observed in semiarid areas (Famiglietti et al., 1999; Lawrence and Hornberger, 2007; Fernández and Ceballos, 2003; Vivoni et al., 2008b; Mascaro et al., 2011), as heterogeneities related ET and soil moisture observations at single sites. A number of studies, however, have shown that accounting for the spatial variability of land surface states is important to vegetation, terrain position and soil properties progressively lead properly identify the linkage with EC measurements (e.g., Detto et al., 2006; Vivoni et al.,
In other words, aggregated turbulent fluxes should be compared to larger spatial differences within a watershed. Soil spatially-averaged surface states obtained at commensurate measurement scales. As a result, CRNS soil moisture variability also impacts land-atmosphere interactions by influencing soil evaporation and plant transpiration. $ET$ measurements using the EC technique also have an intermediate spatial scale depending on wind speed and direction, atmospheric stability, and instrument and surface roughness heights (e.g., Hsieh et al., 2000; Kormann and Meixner, 2001; Falge et al., 2002). Thus, the use of the CRS method and a distributed sensor network estimates could yield valuable information on how be useful to improve the characterization of the relation between evapotranspiration flux and soil moisture and its spatial variability affect evapotranspiration losses. Furthermore, the relation between $ET$ and soil moisture is an important parameterization in models (e.g., Laio et al., 2001; Rodríguez-Iturbe and Porporato, 2004; Vivoni et al., 2008a), which could be improved at intermediate spatial scales through a link between the spatial variability of soil moisture and the aggregated evapotranspiration flux. To our knowledge, soil moisture estimates from the CRNS technique have not been used to study the hydrological processes occurring in small watersheds overlapping with the measurement footprint or for improving the parameterization of land surface models.

In this contribution, we study the soil moisture dynamics of two small semiarid watersheds in Arizona and New Mexico through a comparison of the CRS method instrumented with a distributed sensor network and estimates from closing the water balance at each site. To our knowledge, this is the first study where CRS measurements are validated to two independent methods at the small watershed scale cosmic-ray neutron sensor, an eddy covariance tower, a runoff flume and a network of soil moisture sensor profiles. The two watersheds represent the
heterogeneous vegetation and soil conditions observed in the Sonoran and Chihuahuan Deserts of the southwestern U.S. (Templeton et al., 2014; Pierini et al., 2014). Given the simultaneous observations during the study period (March 2013 to September 2014, 19 months) at both sites, we first compare the CRNS method with the distributed sensor network and estimates from a novel method based on closing the water balance at each site. Given the simultaneous observations during the study period (March 2013 to September 2014, 19 months), we quantify the variations in vadose zone hydrological processes (e.g., infiltration, plant water uptake, leakage, evapotranspiration, percolation) that differentially occur at each site in response to varying precipitation. Combining these various measurement techniques also affords the capacity to construct and compare relationships between the spatially-averaged CRNS estimates and the spatial variability of soil moisture in the measurement footprint as well as with the spatially-averaged ET obtained from the EC method. Finally, by complementing the CRS and EC observations with the distributed sensor network, we propose and test an analytical relation that describes how evapotranspiration varies with the spatial variability of soil moisture. To our knowledge, this is the first study where CRNS measurements are validated via two independent methods at the small watershed scale and used to make new inferences about watershed hydrological processes.

2. Methods

2.1. Study Sites and Their General Characteristics

The two study sites are long-term experimental watersheds in semiarid ecosystems of the southwestern United States. Watershed monitoring began in 1975 at the Santa Rita Experimental Range (SRER), located 45 km south of Tucson, Arizona, in the Sonoran Desert (Fig. 1), as described by Polyakov et al. (2010) and Scott (2010). Precipitation at the site varies considerably
during the year, with 54% of the long-term mean amount (364 mm/yr) occurring during the summer months of July to September due to the North American monsoon (Vivoni et al., 2008a; Pierini et al., 2014). Soils at the SRER site are a coarse-textured sandy loam (Anderson, 2013) derived from Holocene-aged alluvium from the nearby Santa Rita Mountains. The savanna ecosystem at the site consists of the velvet mesquite tree (*Prosopis velutina* Woot.), interspersed with grasses (*Eragrostis lehmanniana, Bouteloua rothrockii, Muhlenbergia porteri* and *Aristida glabrata*) and various cacti species (*Opuntia spinosior, Opuntia engelmannii* and *Ferocactus wislizeni*). Similarly, watershed monitoring began in 1977 at the Jornada Experimental Range (JER), located 30 km north of Las Cruces, New Mexico, in the Chihuahuan Desert (Fig. 1), as described by Turnbull et al. (2013). Mean annual precipitation at the JER is considerably lower than SRER (251 mm/yr), with a similar proportion (53%) occurring during the summer monsoon (Templeton et al., 2014). Soils at the JER site are primarily sandy loam with high gravel contents (Anderson, 2013) transported from the San Andreas Mountains. The mixed shrubland ecosystem at the site consists of creosote bush (*Larrea tridentata*), honey mesquite (*Prosopis glandulosa* Torr.), several grass species (*Muhlenbergia porteri, Pleuraphis mutica* and *Sporobolus cryptandrus*), and other shrubs (*Parthenium incanum, Flourensia cernua* and *Gutierrezia sarothrae*). Fig. 2 presents a vegetation classification at each site grouped into major categories: (1) SRER has velvet mesquite (labeled mesquite), grasses, cacti (*Opuntia engelmannii* or prickly pear) and bare soil, while (2) JER has honey mesquite (labeled mesquite), creosote bush, other shrubs, grasses and bare soil. Table 1 presents the vegetation and geomorphological terrain properties for the site watersheds obtained from 1-m digital elevation models (DEM) and 1-m vegetation maps (Fig. 2). Pierini et al. (2014) and Templeton et al. (2014) describe the image
acquisition and processing methods employed to derive these products at SRER and JER, respectively.

2.2. Distributed Sensor Networks at the Small Watershed Scale

Long-term watershed monitoring at the SRER and JER sites consisted of rainfall and runoff observations at Watersheds 7 and 8 (SRER, 1.25 ha) and the Tromble Weir (JER, 4.67 ha). Pierini et al. (2014) and Templeton et al. (2014) describe recent monitoring efforts using a network of rainfall, runoff, soil moisture and temperature observations, as well as radiation and energy balance measurements at EC towers, commencing in 2011 and 2010 at SRER and JER. This brief description of the distributed sensor networks is focused on the spatially-averaged measurements used for comparisons to the CRNS method. Precipitation ($P$) was measured using multiple-up to 4 tipping-bucket rain gauges (TE525MM, Texas Electronics) to construct a 30-min resolution spatial average based on Thiessen polygons within the watershed boundaries. At the watershed outlets, streamflow ($Q$) was estimated at Santa Rita supercritical runoff flumes (Smith et al., 1981) using a pressure transducer (CS450, Campbell Scientific Inc.) and an in-situ linear calibration to obtain 30-min resolution observations. Evapotranspiration ($ET$) was obtained at 30-min resolution using the EC technique that employs a three-dimensional sonic anemometer (CSAT3, Campbell Scientific Inc.) and an open path infrared gas analyzer (LI-7500, LI-COR Inc.) installed at 7-m height on each tower. Flux corrections for the EC measurements followed Scott et al. (2004) and were verified using an energy balance closure approach reported in Table 2 for the study period. Energy balance closure at both sites is within the reported values across a range of other locations where the ratio of $\Sigma(\lambda E + H)/\Sigma(R_n - G)$ has an average value of 0.8 (Wilson et al., 2002; Scott, 2010). To summarize these observations, Fig. 3 shows the spatially-averaged $P$, $Q$ and $ET$ (mm/hr), each aggregated to hourly resolution, at each study site during
March 1, 2013 to September 30, 2014, along with seasonal precipitation amounts. While the results compare favorably to previous measurements (Turnbull et al., 2013; Pierini et al., 2014; Templeton et al., 2014), it should be noted that $ET$ and $Q$ data are assumed to represent the spatially-averaged watershed conditions, despite the small mismatch between the watershed boundaries and EC footprints (Fig. 2) and the summation of $Q$ in the two watersheds at SRER.

Distributed soil moisture measurements were obtained using soil dielectric probes (Hydra Probe, Stevens Water) organized as profiles (sensors placed at 5, 15 and 30 cm depths) in each study site as Profiles were originally installed at multiple locations along transects to investigate the different primary controls on soil moisture at each site: (1) at SRER, we installed three four transects of 5 profiles each located under different vegetation classes (mesquite, grass, prickly pear and bare soil), and (2) at JER, we established three transects of 5 profiles each installed along different hillslopes (north-, south- and west-facing), as shown in Fig. 1. As described in Campbell (1990), individual sensors measure the impedance of an electric signal through a 40.3 cm$^3$ soil volume (5.7 cm in length and 3.0 cm in diameter) to determine the volumetric soil moisture ($\theta$) in m$^3$/m$^3$ and soil temperature in ºC as 30-min averaged values. A ‘loam’ calibration equation was used in the conversion to $\theta$ (Seyfried et al., 2005) and corrected using relations established through gravimetric soil sampling at each study site (a power law relation at SRER with $R^2 = 0.99$ and a linear relation at JER with $R^2 = 0.97$), following Pierini (2013). Spatial Given that sensors were originally installed to conduct watershed studies, spatial averaging of the sensor profiles within the watersheds aggregated to an hourly resolution was performed using a-site specific weighting schemes schemes accounting for each site based on the main controls on the soil moisture distribution depending on watershed characteristics. Thus: (1) at SRER, we utilized the percentage area of each vegetation class
(Table 1) and the associated sensor locations within each type (Pierini et al., 2014), and (2) at JER, we accounted for the aspect and elevation at the sensor locations and used these to extrapolate to other locations with similar characteristics based on the 1-m DEM (Templeton et al., 2014).

2.3. Cosmic-ray Soil Moisture Neutron Sensing Method for Soil Moisture Estimation

The CRNS method relates soil moisture to the density of fast or moderated neutrons (Zreda et al., 2008) measured above the soil surface. A cosmic-ray neutron sensor (CRS-1000/B, Hydroinnova LLC) was installed in each watershed in January 2013 to record neutron counts at hourly intervals. We selected the study period (March 1, 2013 to September 30, 2014) to coincide with the availability of data from the distributed sensor networks. While the theory of using neutrons for soil moisture measurements has a long history (e.g., Gardner and Kirkham, 1952), recent developments in the measurement of neutrons generated from cosmic rays has increased the horizontal scale, reduced the need for manual sampling, and led to a non-invasive approach. Zreda et al. (2008) and Desilets and Zreda (2013) describe the horizontal scale as having a radius of ~300 m at sea level and a vertical aggregation scale ranging from 12 to 76 cm depending on soil wetness, while the work of Köhli et al. (2015) found a smaller horizontal scale with a radius of ~230 m at sea level. Since the travel speed of fast neutrons is >10 km/s, neutron mixing occurs instantaneous in the air above the soil surface (Glasstone and Edlund, 1952), providing a well-mixed region that can be sampled with a single detector.

Using a particle transport model, Desilets et al. (2010) found a theoretical relationship between the neutron count rate at a detector and soil moisture for homogeneous SiO2 sand:

\[
\theta(N) = \frac{0.0808}{\left(\frac{N}{N_o}\right) - 0.372} - 0.115, \quad (21)
\]
where $\theta$ (m$^3$/m$^3$) is volumetric soil moisture, $N$ is the neutron count rate (counts/hr) normalized to the atmospheric pressure and solar activity level, and $N_0$ (counts/hr) is the count rate over a dry soil under the same reference conditions. The corrections applied to the neutron count rate are detailed in Desilets and Zreda (2003) and Zreda et al. (2012) and are applied automatically in the COSMOS website (http://cosmos.hwr.arizona.edu/). Additionally, since neutron counts are affected by all sources of hydrogen in the support volume, we apply a correction ($C_{WV}$) for atmospheric water vapor that was derived by Rosolem et al. (2013) as:

$$C_{WV} = 1 + 0.0054 \left( \rho_v^o - \rho_v^{\text{ref}} \right),$$

where $\rho_v^o$ (g/m$^3$) and $\rho_v^{\text{ref}}$ (g/m$^3$) are absolute water vapors at current and reference conditions.

To estimate $N_0$, we performed a manual soil sampling at 18 locations within the CRNS footprint (sampled every 60 degrees at radial distances of 25, 75 and 200 m from the detector) at 6 depths (0-5, 5-10, 10-15, 15-20, 20-25, 25-30 cm) for a total of 108 samples per site. Gravimetric soil moisture measurements were made following oven drying at 105 ºC for 48 hrs (Dane and Topp, 2002) and converted to volumetric soil moisture using the soil bulk density (1.54 ± 0.18 g/cm$^3$ at SRER and 1.3 ± 0.15 g/cm$^3$ at JER). The spatially-averaged volumetric soil moisture was related to the average neutron count obtained for the same time period (6-hr average) resulting in $N_o = 3973$ at SRER and $N_o = 4724$ at JER, considered to be in line with the expected amounts given the elevations of both sites (Table 1) compares the gravimetric measurements and the CRNS soil moisture estimates during the calibration dates and provides further details on the soil properties at the two sites. We applied a 12-hr boxcar filter, which ignored rainfall periods with large increase in $\theta$, to the measured count rates to remove the statistical noise associated with the measurement method (Zreda et al., 2012). On days where soil moisture changed by more than 0.06 m$^3$/m$^3$ due to rainfall, the boxcar filter was not applied. We
note that additional terms to the calibration accounting for variations in lattice water, soil organic carbon and vegetation have been proposed (Zreda et al., 2012; Bogena et al., 2013; McJannet et al., 2014; Coopersmith et al. 2014). However, given the relatively small amount of biomass (~2.5 kg/m² at SRER, Huang et al., 2007; and ~0.5 kg/m² at JER, Huenneke et al., 2001), low soil organic carbon (4.2 mg C/g soil at SRER; and 2.7 mg C/g soil at JER, Throop et al., 2011), and low clay percent (5.4% at SRER; and 4.89% at JER, Anderson, 2013), and thus low lattice water amounts (Greacen, 1981), we have neglected these small terms in the analysis. In addition, since a local calibration was performed, lattice water, biomass, and soil organic carbon are implicitly accounted for in the calculation of volumetric soil moisture from the calibration relation.

Fig. 2 presents the horizontal aggregation scale of the CRSCRNS method in comparison to the watershed boundaries and to the EC footprints obtained for summer 2013 (Anderson, 2013). Since both the CRSCRNS and EC footprints have horizontally-decaying contributions, we limited the size of the analysis region to the 50% contribution or source area. While the CRS horizontal footprint is nearly fixed in time at a 120 m radius at SRER and 125 m radius at JER for the 50% contribution, to enhance the overlap with the watershed boundaries and sensor networks. The footprints for both the CRNS method and the EC footprint vary considerably (Anderson, 2013; Köhli et al., 2015), with temporal changes occurring in the amount of overlap with the watersheds and CRS footprints between each other. Nevertheless, the vegetation distributions sampled in the CRSCRNS, EC, and watershed areas (Fig. 2) are nearly the same (Vivoni et al., 2014), and the soils have low spatial variability (Anderson, 2013; Table 3), such that CRSCRNS and EC measurements are considered representative of the watershed conditions. In contrast to the fixed horizontal scale, the CRSCRNS method
measures a time-varying vertical scale that depends on the soil water content. Franz et al. (2012b) used a particle transport model to determine that the CRNS measurement depth, \( z^* \), varied with soil moisture as:

\[
\begin{align*}
z^*(\theta) &= \frac{5.8}{\rho_b \tau + \theta + 0.0829}, \\
\end{align*}
\]

where \( \rho_{bd} \) is dry bulk density of the soil (1.535 g/cm\(^3\) at SRER and 1.300 g/cm\(^3\) at JER Table 3) and \( \tau \) is the weight fraction of lattice water in the mineral grains and bound water. Lattice water must be considered here since a local calibration of (3) is not possible. As a result, lattice water content was established at 0.02 g/g at each site given the weathered soils (and the measurements from Franz et al., 2012b). To account for the temporal variation of \( z^* \), the distributed sensor profiles representing different soil layers (0-10 cm, 10-20 cm, and 20-40 cm in depth) were weighted based on \( z^* \) at each hourly time step according to:

\[
wt(z) = a \left( 1 - \left( \frac{z}{z^*} \right)^b \right) \quad \text{for} \quad 0 \leq wt \leq z^*,
\]

where \( wt(z) \) is the weight at depth \( z \), \( a \) is a constant defined to integrate the profile to unity (\( a = 1/(z^* - \{z^*b\}/[z^b(1 + 1)]) \)), and \( b \) controls the shape of the weighting function. For simplicity, we assumed a value of \( b = 1 \) leading to a linear relationship (Franz et al., 2012b).

2.4. CRS and

3. Methods

3.1. Comparison of CRNS to Distributed Sensor Network Analyses Methods of Soil Moisture Sensors

We The CRNS method was first validated against the distributed network of soil moisture sensors. As done in previous studies, we compared hourly soil moisture observations obtained from the CRNS method (\( \theta_{CRS}, \theta_{CRNS} \)) to estimates from the distributed sensor
network ($\theta_{SN}$) that have been averaged in space (i.e., based on vegetation type at SRER and
elevation/aspect location at JER) and depth-weighted according to the time-varying CRS measurement depth ($z^*$). We also assessed the CRS method relative to estimates from closing the water balance (1) using spatially-averaged $P$, $Q$ and $ET$. For this comparison, the change in soil moisture from the water balance ($\Delta \theta_{WB}$) was compared to $\Delta \theta_{CRS}$, both calculated as differences over the time scale of a rainfall event and its soil moisture response (i.e., the change from pre-storm soil moisture to the peak amount due to a rainfall event). This relative comparison assumes used several metrics to quantitatively assess the comparisons, including Root Mean Square Error (RMSE), Correlation Coefficient (CC), Bias (B) and Standard Error of Estimates (SEE). We performed an effective soil measurement depth ($z_m$) of 40 cm determined as the time-averaged $z^*$ from the CRS method at each site. Since this comparison is performed over a short time interval during the rising limb of the soil moisture response, we tested whether the assumption of no leakage (i.e., $L = 0$) is valid given that there are small losses below $z_m$ to the deep vadose zone. Leakage beyond 40 cm is infrequent at both sites during the summer monsoon, but can occur on a time scale of several days during winter precipitation (e.g., Franz et al., 2012b; Templeton et al., 2014; Pierini et al., 2014). We used several metrics to quantitatively assess the comparisons: additional test of the CRNS technique by comparing relations between the mean soil moisture ($<\theta>$), obtained from either $\theta_{CRNS}$ or $\theta_{SN}$, and the spatial standard deviation ($\sigma$) of soil moisture measured in the distributed sensor network. This relation has been studied previously with the CRS method: Root Mean Square Error (RMSE), Correlation Coefficient (CC), Bias (B) and Standard Error of Estimates (SEE). goal of evaluating the role of heterogeneities related to vegetation, terrain position and soil properties (Famiglietti et al., 1999; Lawrence and Hornberger, 2007; Fernández and Ceballos, 2003; Vivoni et al., 2008b; Mascaro
et al., 2011; Qu et al., 2015). Based on Famiglietti et al. (2008), we fitted an empirical function to the observations at each site:

We also calculated a soil water balance based on the CRS method to determine the spatially-averaged fluxes into and out from the measurement depth ($z^*$) as (Franz et al., 2012b):

$$\sigma = k_1 \theta e^{-k_2 \theta}$$  \hspace{1cm} (5)

where $k_1$ and $k_2$ are regression parameters, and compared these to prior studies in the region (e.g., Vivoni et al., 2008b; Mascaro and Vivoni, 2012; Stillman et al., 2014).

### 3.2. CRNS Water Balance Analyses Methods

In small watersheds of comparable size to the CRNS measurement footprint, the water balance can be expressed as:

$$z^* \frac{\Delta \theta}{\Delta t} = P - ET - Q - L$$  \hspace{1cm} (6)

where $f_{\text{CRS}}$ is the daily flux (mm/day) and $\Delta t$ is the time step (1 day). Positive values of $f_{\text{CRS}}$ represent infiltration ($I$) into the measurement depth, while negative values equal outflow ($O$), occurring either as $\Delta \theta$ is the change in volumetric soil moisture over the time interval $\Delta t$. $P$ is precipitation, $ET$ is evapotranspiration or leakage. Based on daily $P$ data, $Q$ is streamflow, and $L$ is leakage or deep percolation, with all of the terms expressed as spatially-averaged quantities and valid over the effective soil measurement depth ($z^*$). The water balance was applied to validate the accuracy of the CRNS observations using measurements of the spatially-averaged fluxes ($P$, $ET$ and $Q$) can be derived as $P - I$, assuming negligible plant interception, and compared to $Q$ measurements in the watersheds. Using the EC method to obtain daily $ET$, $L = Q - ET$ can be obtained as a measure of exchanges between the CRS measurement depth and soil below for a set of storm events. For each event, we computed the change in soil moisture
measured by the CRNS, $\Delta \theta_{CRNS}$, and the change calculated from the water balance, $\Delta \theta_{WB}$. In both cases, changes were computed as the difference between the pre-storm soil moisture and the peak amount due to a rainfall event. For the application of (6), the soil measurement depth $z^*$ is positive when there is leakage to deeper soil layers and negative when deeper water is being drawn to support plant transpiration.

2.5. Soil Moisture Variability and Its Link $^{*}$ was calculated as the average value over the duration of the soil moisture response to each individual storm. Note that, during a storm, $ET$ is very low and the use of $z^*$ in (6) instead of the plant rooting depth is justified. In addition, since this comparison is performed over a short time interval during the rising limb of the soil moisture response, we assumed no leakage (i.e., $L = 0$). To test the validity of this hypothesis, we analyzed the soil moisture records measured at the EC towers, where sensors were installed to Evapotranspiration measure the profile up to 1 m (i.e., a depth larger than $z^*$). We found that the percolation beyond a depth of ~40 cm is infrequent at both sites during summer monsoon storms, thus sustaining our assumption. However, percolation can occur on a time scale of several days during winter precipitation (e.g., Franz et al., 2012b; Templeton et al., 2014; Pierini et al., 2014). Although there are large amounts of bare soil in the watersheds, shrub and tree roots have been shown to extend laterally for 10 m or more (Heitschmidt et al., 1988), such that most of contributing area will be under the influence of both bare soil evaporation and plant transpiration.

The spatial variability within the CRS footprint was assessed using the distributed sensor network by constructing relations between the spatial standard deviation ($\sigma$) and coefficient of variation ($CV = \sigma/\langle \theta \rangle$) with the mean soil moisture state ($\langle \theta \rangle$), obtained either from the CRS method ($\theta_{CRS}$) or Once validated against the distributed sensor network ($\theta_{SN}$). Based on the
methods—sensors and the application of the water balance, the CRNS estimates were subsequently
used to determine the daily spatially-averaged fluxes into and out from the measurement depth
\((z^*)\) as proposed by FamigliettiFranz et al. (2008), we fitted the following empirical functions to
the observations at each site:2012b):

\[
f_{\text{CRNS}}(t) = \left( \theta_{\text{CRNS},t} - \theta_{\text{CRNS},t-1} \right) \min(z^*, z^*_{t-1}) / \Delta t \quad \text{and} \quad CV = k_1 e^{-k_2(t)}
\]

(7) (8)

where \(k_1\) and \(k_2\) are regression parameters, and compared these to prior studies in the region (e.g.,
Vivoni et al., 2008b; Mascaro and Vivoni, 2012; Stillman et al., 2014). Soil moisture at single
locations is typically linked to In (7), \(f_{\text{CRNS}}\) is the daily flux (mm/day), \(\Delta t\) is the time step (1 day),
and \(\min(z^*, z^*_{t-1})\) represents the minimum daily-averaged measurement depth between the two
days being compared. Positive values of \(f_{\text{CRNS}}\) indicate an increase in soil moisture and, thus,
represent net infiltration \((f_{\text{CRNS}} = I)\) into the measurement depth, usually occurring after a rainfall
event. As a result, assuming negligible plant interception, daily \(P\) data can be used to estimate \(O\)
as \(P - I\), which in turn can be compared to the runoff measurements in the watersheds. On the
other hand, negative values of \(f_{\text{CRNS}}\) are equal to the net outflow \((f_{\text{CRNS}} = O)\), which can occur
either as evapotranspiration or leakage. Using the EC method to obtain daily \(ET\), \(L = O - ET\) can
be determined as a measure of exchanges between the soil layers above and below \(z^*\): \(L\) is
positive when there is drainage to deeper soil layers and negative when deeper water is being
drawn to support plant transpiration.

3.3. Relation between Evapotranspiration and Soil Moisture at Commensurate Scale
Soil moisture at single locations is typically linked to $ET$ in hydrologic models (e.g., Chen et al., 1996; Ivanov et al., 2004) and empirical studies (e.g., Small and Kurc, 2003; Vivoni et al., 2008a) using relations such as $ET = f(\theta)$. For example, a commonly used approach is based on a piecewise linear relation between daily $ET$ and $\theta$ (Rodríguez-Iturbe and Porporato, 2004):

$$ET(\theta) = \begin{cases} 
0 & 0 < \theta \leq \theta_h \\
E_w \frac{\theta - \theta_h}{\theta_w - \theta_h} & \theta_h < \theta \leq \theta_w \\
E_w + (ET_{\text{max}} - E_w) \frac{\theta - \theta_h}{\theta^* - \theta_h} & \theta_w < \theta \leq \theta^* \\
ET_{\text{max}} & \theta^* < \theta \leq \phi
\end{cases},$$

where $E_w$ is soil evaporation, $ET_{\text{max}}$ is maximum evapotranspiration, $\theta_h$, $\theta_w$, and $\theta^*$ are the hygroscopic, wilting and plant stress soil moisture thresholds, and $\phi$ is the soil porosity. Vivoni et al. (2008a) applied (9) to observations of $ET$ from the EC method and $\theta$ at single locations to derive the relation parameters using a nonlinear optimization algorithm (Gill et al., 1981). We evaluate this approach using the spatially-averaged soil moisture estimates ($\theta_{\text{CRS}}$, $\theta_{\text{CRNS}}$, and $\theta_{\text{SN}}$) whose spatial scale is more commensurate with the $ET$ measurements. In addition, we combine (9) with (7) and (8) to obtain analytical relations between evapotranspiration and the spatial variability of soil moisture, $ET = f(\sigma)$ and $ET = f(CV)$, and test these with $\theta_{\text{CRS}}$ and $\theta_{\text{SN}}$ observations than single measurement sites.

### 3.4. Results and Discussion

#### 3.4.1. Comparison of CRS\-CRNS Method to Distributed Sensor Network

Fig. 4 presents a comparison of the spatially-averaged, hourly soil moisture obtained from the CRS\-CRNS method ($\theta_{\text{CRS}}$, $\theta_{\text{CRNS}}$) and the distributed sensor network ($\theta_{\text{SN}}$) during the study period, as well as the time-varying measurement depth ($z^*$) of CRNS. Relative to the long-term summer precipitation (Table 1), the study period had below average (188 and 153 mm...
in 2013 and 2014) and significantly above average (246 and 247 mm) rainfall at SRER and JER, respectively. The fall-winter period in the record had below average precipitation (99 mm) at SRER and significantly below average amounts (21 mm) at JER. Overall, the spring periods were dry, consistent with the long-term averages. In response, the temporal variability of soil moisture clearly shows the seasonal conditions at the two sites, with relatively wetter conditions during the summer monsoons. Seasonally-averaged $\theta_{CRS}$ and $\theta_{CRNS}$ compares favorably with seasonally-averaged $\theta_{SN}$ (Fig. 4), with both estimates showing relatively large differences between wetter summer conditions (0.065 and 0.085 m$^3$/m$^3$ at SRER and JER) and drier spring values (0.028 and 0.021 m$^3$/m$^3$ at SRER and JER, respectively). As shown in prior studies (e.g., Zreda et al., 2008; Franz et al., 2012b), the CRS method tracks very well the sensor observations. Nevertheless, there is an indication that $\theta_{CRS}$ has a tendency to dry less quickly during some rainfall events (i.e., overestimate soil moisture during recession limbs), possibly due to landscape features such as nearby channels (Fig. 1) and their associated zones of soil water convergence that remain wetter than areas measured by the distributed sensor network. Overall, however, there is an excellent match between $\theta_{CRS}$ and $\theta_{SN}$ in terms of capturing the occurrence and magnitude of soil moisture peaks across the different seasons, thus reducing some issues noted by Franz et al. (2012b) with respect to a purported oversensitivity of $\theta_{CRS}$ for small rainfall events (<5 mm). We attribute this improvement primarily to including the use of a 5 cm sensor in each profile that tracks the important soil moisture dynamics occurring in the shallow surface layer within semiarid ecosystems.

To complement this, Fig. 5 compares $\theta_{CRS}$ and $\theta_{SN}$ as a scatterplot along with the sample size (N) and the Standard Error of Estimates (SEE) which quantify the deviations from the 1:1 line. Table 3 provides the full set of statistical metrics for the comparison of $\theta_{CRS}$ and $\theta_{CRNS}$.
versus \( \theta_{SN} \) at the two study sites. The correspondence between both methods is excellent, with low RMSE and SEE, a high CC, and a Bias close to 1. These values are comparable to previous validation efforts where the RMSE was found to be 0.011 m\(^3\)/m\(^3\) (Franz et al., 2012b) and less than 0.03 m\(^3\)/m\(^3\) (Bogena et al., 2013; Coopersmith et al., 2014; Zhu et al., 2015). The comparison across the sites is also illustrative. Despite the more arid climate at JER (Table 1), the study period consisted of higher precipitation (247 mm) and higher soil moisture values during the summer (0.085 m\(^3\)/m\(^3\)), as compared to SRER (170 mm, 0.065 m\(^3\)/m\(^3\)), indicating a more active North American monsoon in the Chihuahuan Desert. In contrast, the fall-winter period is generally drier at JER (21 mm, 0.039 m\(^3\)/m\(^3\)), as compared to SRER (99 mm, 0.057 m\(^3\)/m\(^3\)), where high \( P \) and low \( ET \) in the winter promoted infiltration beyond the CRNS measurement depth, as observed at a 1-m sensor profile at SRER (not shown). These two effects lead to a larger range of soil moisture values at JER as compared to SRER in Fig. 5 for JER. It is also worth noting that \( \theta_{CRS} \) has a larger dynamic. As a result, the CRNS method is found to be a reliable method for measuring soil moisture in the observed range for dry conditions (i.e., \( \theta_{CRS} \) values can reach zero, whereas \( \theta_{SN} \) does not), indicating that the values at SRER and JER.

To further test the CRNS method overcomes the measurement limitations discussed by Vereecken et al. (2014). Based on these comparisons, the CRS method is found to be a reliable approach for measuring intermediate scale soil moisture across the observed range of soil moistures at SRER and JER.

3.2. Comparison and Analyses of CRS Method and Water Balance Estimates

Fig. 6 presents the comparison of the spatially averaged \( A\theta_{CRS} \) and \( A\theta_{WB} \) as a scatterplot for approximately 40 rainfall events larger...
than 10 mm, with statistical metrics shown in Table 3. The correspondence between the methods is very good, with low RMSE and SEE, a high CC, and a Bias close to 1, with a closer match at the methods depicts the relations between the spatial variability of soil moisture ($\sigma$) and the spatially-averaged conditions ($<\theta>$). For illustration purposes, bin-averages and standard deviations are also presented for each relation. Least squares regressions of (5) based on hourly observations were applied to estimate $k_1$ and $k_2$ for the relations $\sigma$ vs. $\theta_{SN}$ ($k_1 = 0.75$ and $k_2 = 4.23$ at SRER site. For example, the SEE at SRER (0.020 m$^3$/m$^3$) is about one half of the value; $k_1 = 0.74$ and $k_2 = 2.75$ at JER) and these parameters were adopted to interpret the relations of $\sigma$ vs. $\theta_{CRNS}$. The RMSE are very low and similar in both cases (RMSE = 0.007 and 0.008 m$^3$/m$^3$ at SRER and 0.005 and 0.008 m$^3$/m$^3$ at JER (0.049 m$^3$/m$^3$) and close to the SEE of the comparison of $\theta_{CRS}$ and $\theta_{SN}$. This suggests that the three approaches for estimating soil moisture are in agreement at the SRER. For the JER, the lower correspondence between $\Delta \theta_{CRS}$ and $\Delta \theta_{WB}$ is attributed to five large events where $\Delta \theta_{WB}$ is above 0.2 m$^3$/m$^3$. Removing these events lowers the SEE at JER to 0.020 m$^3$/m$^3$, in line with SRER and the comparison of $\theta_{CRS}$ and $\theta_{SN}$ at JER. A closer inspection of the soil moisture response at JER is revealing. Fig. for the relation with $\theta_{SN}$ and $\theta_{CRNS}$, respectively), thus confirming the good correspondence between the two methods. As shown in prior efforts in semiarid ecosystems using sensor networks or aircraft observations (e.g., Fernández and Ceballos, 2003; Vivoni et al., 2008b; Mascaro et al., 2011; Stillman et al., 2014), there is a general increase in $\sigma$ with $<\theta>$, explained by the role played by local heterogeneities (e.g., vegetation types, surface soil variations, topography) as well as the bounded nature of the soil moisture process at the driest state. The similar relations derived in these different sites might be broadly applicable to other semiarid ecosystems in the southwestern U.S.

### 4.2. Validation of CRNS Method with Water Balance Estimates
Fig. 7 presents the comparison of the spatially-averaged $\Delta \theta_{CRNS}$ and $\Delta \theta_{WB}$ as a scatterplot for approximately 40 rainfall events with a total depth larger than 10 mm and durations ranging from 0.5 to 31 hours (mean of 6 hours). The statistical metrics are presented in Table 4. The correspondence between the methods is very good, with low RMSE and SEE, a high CC, and a Bias close to 1, with a closer match at SRER. For example, the SEE at SRER (0.024 m$^3$/m$^3$) is significantly less than the value at JER (0.095 m$^3$/m$^3$) and close to the SEE of the comparison of $\theta_{CRNS}$ and $\theta_{SN}$. This suggests that the three approaches (i.e., CRNS, sensor network, water balance) are in agreement at the SRER. For the JER, the lower correspondence between $\Delta \theta_{CRNS}$ and $\Delta \theta_{WB}$ is attributed to five large events where $\Delta \theta_{WB}$ is above 0.2 m$^3$/m$^3$. Removing these events lowers the SEE at JER to 0.020 m$^3$/m$^3$, in line with SRER and the comparison of $\theta_{CRNS}$ and $\theta_{SN}$ at JER. A closer inspection of the soil moisture response at JER allows investigating the physical reasons causing the different behavior of these five events. Fig. 8 shows the soil moisture change ($\Delta \theta_{SN}$) at different sensor depths averaged for the selected large events and for the remaining events, as well as the mean of CRNS measurement depths ($z^*$) for each case. The five large events exhibit high soil moisture changes at 30 cm depth (i.e., 0.08 m$^3$/m$^3$) below $z^*$ (i.e., 17 cm), while other events have soil moisture changes near zero at 30 cm and are captured well within $z^*$. This indicates that infiltration fronts during the larger events penetrated beyond $z^*$ and were not entirely captured by the CRNS method, leading to an underestimate of $\Delta \theta_{WB}$. For these events, the assumption $L=0$ in equation (6) is not fully supported. In contrast, the better correspondence at SRER suggests that infiltration fronts were contained within $z^*$ (see Table 3). This is plausible given the more homogeneous soil and flatter terrain at SRER as compared to JER (Anderson, 2013). At JER, soil water movement to deeper layers can be promoted by higher gravel contents and the presence of calcium carbonate and
undulated terrain can promote soil water movement to deeper layers which facilitate lateral water transfer to channels with sandy bottoms (Templeton et al., 2014).

To explore this further,

4.3. Utility of CRNS for Investigating Hydrological Processes

Given the confidence gained with respect to the CRNS estimates, we utilized these observations to quantify the water balance fluxes during storm and interstorm periods at the two sites. Fig. 8 shows the cumulative $f_{CRS}$ and the cumulative, spatially-averaged $P$ and $ET$ measured by the distributed sensor network. An overall drying trend is present at SRER during the study period (i.e., cumulative $f_{CRS}$ becomes more negative), while JER exhibits a relatively small change in cumulative $f_{CRS}$, both in response to the below average (SRER) and above average (JER) precipitation. An important contrast at the sites is the overall water balance (Table 4), where higher $P$, lower $ET$, and lower $Q$ at JER (measured $ET/P = 0.54$, $Q/P = 0.01$) implies that more soil water is available for leakage to deeper soil layers. This is reflected in a large positive difference between cumulative outflow ($O = ET + L$) and $ET$ at JER (i.e., $L > 0$ from $z^*$, soil water movement to lower layers, as depicted in the soil water balance diagram). In contrast, SRER exhibits a higher $ET/P = 0.96$ and $Q/P = 0.14$, such that negative differences occur between $O$ and $ET$ (i.e., $L < 0$ into $z^*$, movement from lower layers, as depicted in the soil water balance diagram). This is particularly important during the summers when vegetation is active and draws more $ET$ than the outflow from the CRS measurement depth, indicating that soil water is obtained from deeper soil layers that are readily accessed by velvet mesquite roots (e.g., Snyder and Williams, 2003; Scott et al., 2008; Potts et al., 2010). This is consistent with the sustained $ET$ during interstorm periods in the summer season at SRER despite the low $\theta_{CRS}$, while JER exhibits sharp declines in $ET$ when $\theta_{CRS}$ is reduced between storms.
Overall, the soil water balance from the CRSCRNS method shows stark ecosystem differences at the two sites during the study period. The mesquite savanna at SRER extracted substantial amounts of water from deeper soil layers during the summer season such that losses to runoff and the atmosphere are in excess of seasonal precipitation. It is likely that the deeper soil water is recharged beyond the CRSCRNS measurement depth during winter periods (as observed by Scott et al., 2000) and subsequently accessed by deep-rooted trees during the summer (Scott et al., 2008). In contrast, the mixed shrubland at JER lost a substantial amount of precipitation to deeper soil layers throughout the year, due to the low values of runoff and evapotranspiration, and the soil, terrain and channel conditions promoting recharge (Templeton et al., 2014). Winter recharge is fostered by the lack of ET from drought-deciduous plants that lose their leaves in the wintertime. We hypothesize that deep percolation is likely occurring in the channels, since: (i) soil moisture observations in the hillslopes (i.e., far from the channel) show a lack of deep percolation, (ii) the runoff ratio decreases with the basin contributing area, indicating transmission losses along the channel (Templeton et al., 2014), and (iii) one sensor profile installed in a channel at SRER shows that the wetting front frequently reaches at least 30 cm depth. Furthermore, the fCRSCRNS approach provided estimates that can be compared to the watershed water balance since these are at a similar spatial scale (Table 4). Estimates of outflow (O) from the measurement depth and leakage (L) are higher when calculated with $\theta_{SN}$, consistent with more rapid drying as compared to the CRSCRNS method. On the other hand, the CRSCRNS method results in higher values of the runoff ratio ($Q/P$) than observed in the distributed sensor network, in particular for JER. This is likely due to the daily scale of the CRSCRNS analysis, which significantly limits the suitability of the runoff estimate for semiarid watersheds characterized by runoff responses lasting minutes to hours.
3.3. Soil Moisture Spatial Variability within CRS Footprint

Fig. 9 depicts the relations between the absolute ($\sigma$) and relative ($CV$) spatial variability of soil moisture and the spatially-averaged conditions ($<\theta>$) derived from either $\theta_{SN}$ or $\theta_{CRS}$ at each study site. Least squares regressions of (7) and (8) based on hourly observations were used to obtain $k_1$ and $k_2$, as shown in Table 5. For illustration purposes, bin averages and standard deviations are also presented for each relation. As shown in prior efforts in semiarid ecosystems using sensor networks or aircraft observations (e.g., Fernández and Ceballos, 2003; Vivoni et al., 2008a; Mascaro et al., 2011), there is a general increase in $\sigma$ with $<\theta>$ and a decrease of $CV$ with $<\theta>$. The increase in spatial variability of soil moisture in absolute terms with wetter conditions is explained by the role played by local heterogeneities (e.g., vegetation types, surface soil variations, topography) as well as the bounded nature of the soil moisture process at the driest state (i.e., spatial variations are small in absolute terms when an area is very dry). Interestingly, both sites exhibit an asymptotic $\sigma$ for the wettest values (above $0.1 \text{ m}^3/\text{m}^3$ at SRER and $0.15 \text{ m}^3/\text{m}^3$ at JER), as more clearly observed for $\theta_{SN}$, indicating that the summer monsoon has wet soil moisture states that might be described as sub-humid, following the classification of Lawrence and Hornberger (2007). The observed relations of $\sigma$-<\theta> and $CV$-<\theta> at both sites are captured well by the exponential functions (7 and 8) leading to a low RMSE. Furthermore, a bootstrap analysis based on a random removal 100 points was conducted to generate 95% level confidence intervals for $k_1$ and $k_2$. We found that the set of $k_1$ and $k_2$ obtained is included within the confidence intervals for both $\theta_{SN}$ or $\theta_{CRS}$. This indicates the relations derived in these different sites might be broadly applicable to other semiarid ecosystems in the southwestern U.S. Nevertheless, there are some small discrepancies between the relations obtained for $\theta_{SN}$ and $\theta_{CRS}$ and the regressions parameters were shown to be
significantly different at the 95% confidence interval through a similar bootstrap analysis. We attribute these differences to the asymptotic behavior at the wettest states occurring after a rainfall event when $\theta_{CRS}$ has a slightly higher value than $\theta_{SN}$, likely due to the instantaneous contribution of water above the ground surface (e.g., water in channels, surface depressions or on vegetation canopies).

**3.4. Controls of Soil Moisture and Its Spatial Variability on Evapotranspiration**

Fig. 10 compares the relationships between the measured daily $ET$ using the EC method and the spatially-averaged soil moisture values ($\theta_{SN}$ and $\theta_{CRS_{CRNS}}$) at the SRER and JER sites along with the piecewise linear regressions estimated using (9) and a nonlinear optimization approach. Following Vivoni et al. (2008a), regression parameters related to soil and vegetation conditions are presented in Table 6. For illustration purposes, bin-averages and standard deviations are also shown. Clearly, the piecewise linear relation is an excellent approach for capturing the $ET$-$\theta$ observations, yielding a relatively low RMSE at the two sites. A lower RMSE for the relation using $\theta_{CRS_{CRNS}}$ as compared to $\theta_{SN}$ at SRER is attributed to its ability to detect a wider range of dry conditions and the improved match in the spatial scales of $ET$ and $\theta_{CRS_{CRNS}}$, in an analogous fashion to the comparison between a single sensor and the distributed sensor network (Templeton et al., 2014). In addition, the $\text{CRS}_{\text{CRNS}}$ method represents soil evaporation ($E_w$) in a more realistic way as it discriminates differences in drier states, illustrated by the realistic gradual increase of bare soil evaporation with increasing soil water (Fig. 10). For $ET$ and $\theta_{SN}$, the dry portions of the relations have too steep of a slope and do not represent well how bare soil evaporation changes with soil moisture. When comparing both sites through the $ET$-$\theta$ relation, the SRER has a larger $E_w$ and $ET_{max}$ and lower $\theta^*$, as compared to JER, tested to be significantly different at the 95% confidence level using a bootstrap
approach. Together, these parameters indicate that SRER has a higher overall $ET$, consistent with higher extractions from the CRNCRNS measurement depth due to the mesquite trees, extensive grass cover and higher soil evaporation.

We explore whether a daily relationship exists between the absolute ($\sigma$) and relative ($CV$) spatial variability of soil moisture and evapotranspiration in Fig. 11. Daily observations and bin-averages with standard deviations are derived entirely from the distributed sensor network and EC measurements. Given the relations linking $\sigma$ and $ET$ with the mean soil moisture (Figs. 9 and 10), the $ET-\sigma$ relations exhibit an increase in $ET$ with higher-$\sigma$ at both sites, though this is clearer at JER.

5. Summary and Conclusions

In this study, we utilized distributed sensor networks to examine the cosmic-ray neutron sensing soil moisture method at the small watershed scale in two semiarid ecosystems of the southwestern U.S. To our knowledge, this is the first study to compare CRNS measurements to two complementary approaches for obtaining spatially-averaged soil moisture at a commensurate scale: (1) a distributed set of sensor profiles weighted in the horizontal and vertical scales within each watershed, and (2) a watershed-averaged quantity obtained from closing the water balance. We highlighted a few novel advantages of the CRNS method revealed through the comparisons, including the ability to resolve the shallow soil moisture dynamics and to match the estimates obtained from closing the water balance for most rainfall events. In the distributed sensor comparisons, we found that the CRNS method overestimated soil moisture during the recession limbs of rainfall events, possibly due to the wider range of $\theta_{SN}$. This indicates that high absolute variability of soil moisture is associated with larger $ET$, likely due to the growth of wet patches supporting progressively more evapotranspiration. In contrast, the $ET-CV$ relations exhibit a weaker negative trend such that a higher relative variability implies a lower $ET$. This occurs due to the role of the mean soil moisture state landscape features such that dry conditions have a relatively-high $CV$ (Fig. 9) and support a low $ET$ (Fig. 10). Observations are compared to the
analytical relations obtained by combining (9) with (7) and (8) using $\theta_{CRS}$ as the spatially-averaged value for $ET-\sigma$ and $ET-CV$, respectively (solid lines). While the analytical relations approximate the data fairly well, it is clear that the $ET_{\text{max}}$ limit (horizontal lines) does not represent the growth of $ET$ with higher $\sigma$ and lower $CV$. Nevertheless, the analytical functions are a promising application of the CRS method that can yield valuable information for understanding land-atmosphere interactions, under the assumption the $\sigma-<\theta>$ and $ET-\theta$ relations have been established (e.g., Table 5 and 6).

4. Summary and Conclusions

In this study, we utilized distributed sensor networks to examine the cosmic-ray sensing (CRS) soil moisture method at the small watershed scale in two semiarid ecosystems of the southwestern U.S. (Pierini et al., 2014; Templeton et al., 2014). To our knowledge, this is the first study to compare CRS measurements to two complementary approaches for obtaining spatially-averaged soil moisture at a commensurate scale: (1) a distributed set of sensor profiles weighted in the horizontal and vertical scales within each watershed, and (2) a watershed-averaged quantity obtained from closing the water balance. Coordinated efforts at the two small watersheds with varying landscape characteristics and precipitation conditions during the study period afforded the opportunity to conduct comparisons of soil moisture, evapotranspiration and vadose zone processes (infiltration, plant water uptake, as nearby channels remaining wet. In the water balance comparisons, we identified that our assumption of no leakage). We highlighted a few novel advantages of the CRS method revealed through the intercomparisons, including the ability to discriminate dry soil moisture states that is not possible through a sensor network, to resolve the shallow soil moisture dynamics captured well at the 5 cm sensors, and to match the independent soil moisture estimates from closing the water balance for most rainfall events. In
the distributed sensor comparisons, we found that the CRS method overestimated the maximum soil moisture during rainfall events, likely due to the presence of water in surface depressions, plant canopies or channels. In the water balance comparisons, we identified that the CRS beneath \( z^* \) was not met during large rainfall events and the CRNS method was not able to capture the soil moisture conditions during large rainfall events and attributed all of the soil water present. We attribute this to rapid bypassing of the measurement depth promoted by watershed due to soil and terrain characteristics. Due to this observed bypass flow, we suggest that future seasonal water balance studies using the CRNS method include a few soil moisture sensor profiles below \( z^* \) to detect leakage events.

We utilized the CRNS soil moisture estimates were used in combination with the various measurement methods to explore the relative magnitudes of the water balance components at each site given the different precipitation amounts during the study period. The drier than average conditions in the mesquite savanna ecosystem at SRER lead to drier surface soils incapable of supporting the measured evapotranspiration unless supplemented by plant water uptake from deeper soil layers (Scott et al., 2008). In contrast, wetter than average summer periods in the mixed shrubland at JER had wet surface soils that promoted leakage into the deeper vadose zone which was subsequently unavailable for runoff and evapotranspiration losses (Duniway et al., 2010). Comparisons across different seasons at each site also suggested that carryover of soil water from winter leakage toward deeper soil layers is consumed during the summer season by active plants. These novel inferences within the two ecosystems relied heavily on the application of the CRNS method and its limited measurement depth to discriminate between shallow and deeper vadose zone processes as well as on the direct measurement of the water balance components, in particular evapotranspiration from the eddy-covariance technique.
It is important to keep in mind, however, that the ability to resolve watershed-scale hydrologic processes, such as the interaction between shallow and deep soil layers attributed to plant water uptake and leakage, depends to a large degree on the accuracy and representativeness of the distributed sensor network measurements and how their horizontal and vertical scales overlap with the CRNS measurement footprint. We expect these limitations to be especially critical in semiarid ecosystems with high spatial heterogeneity induced by vegetation and bare soil patches.

The collocation of a distributed sensor network within the CRNS measurement footprint also allowed us to examine important process-based relations that are often incorporated into hydrologic models or remote sensing analyses (e.g., Famiglietti and Wood, 1994; Famiglietti et al., 2008). The spatial variability of soil moisture is linked to the spatially-averaged conditions through predictable relations that do not vary significantly across the study sites. For higher mean soil moisture, we observed a nearly linear increase in spatial variability followed by an asymptotic behavior attributed to the seasonally-wet conditions during the North American monsoon. Based on these relations ($k_1$ and $k_2$), the spatial variability within a CRNS measurement footprint can be approximated for other semiarid ecosystems in the region. In addition, combining fixed and mobile CRNS methods can establish landscape scale ($10^2$ to $10^3$ km$^2$) soil moisture monitoring networks at grid sizes (~1 km$^2$) comparable to land surface modeling (Franz et al., 2015). Similarly, intermediate scale soil moisture sensing can be linked effectively to daily evapotranspiration and used to obtain soil and vegetation parameters ($E_w$, $ET_{max}$, $\theta_h$, $\theta_w$, and $\theta^*$) tailored to each ecosystem. In term of the $ET-\theta$ relation, the CRNS method has the potential to significantly improve land-atmosphere interaction studies through the commensurate scale achieved to the EC technique. Furthermore, we found that
analytical relations linking soil moisture spatial variability with evapotranspiration exhibit similar characteristics to the observed datasets. As the spatial variability in soil moisture grows in the two semiarid ecosystems there is a concomitant increase in evapotranspiration. While this suggests that wet patches in a drier background sustain higher atmospheric losses, further investigations are needed to disentangle the individual roles of soil evaporation and plant water uptake on setting both the soil moisture spatial variability and the resulting evapotranspiration averaged in its measurement footprint.

**Figure Captions**

**Fig. 1:** (a) Location of the study sites in Arizona and New Mexico. Watershed representations and sensor locations at (b) SRER and (c) JER, shown at the same scale.

**Fig. 2:** Vegetation classification for (a) SRER and (b) JER derived from aerial image analyses along with sensor locations and the 50% contributing areas of the CRSCRNS and EC footprints.

**Fig. 3:** Hourly precipitation, streamflow and evapotranspiration at the (a) SRER and (b) JER sites during the study period (March 2013 to September 2014). Gaps in ET data indicate periods of EC tower malfunction due to equipment failures, data collection problems or vandalism. Vertical dashed lines indicate the seasonal definitions and their corresponding total precipitation.

**Fig. 4:** Comparison of the spatially-averaged, hourly soil moisture (m$^3$/m$^3$) from CRSCRNS method ($\theta_{CRS\{CRNS}}$, black lines) and distributed sensor network ($\theta_{SN}$, gray lines) at (a) SRER and (b) JER, along with spatially-averaged, hourly precipitation during March 1, 2013 to September 30, 2014. Vertical dashed lines indicate the seasonal definitions and their corresponding seasonally-averaged $\theta_{CRS\{CRNS}}$ and $\theta_{SN}$ in m$^3$/m$^3$. Also shown are the time-varying measurement depths ($z^*$).

**Fig. 5:** Scatterplots of the spatially-averaged, hourly soil moisture (m$^3$/m$^3$) from CRSCRNS method ($\theta_{CRS\{CRNS}}$) and distributed sensor network ($\theta_{SN}$) at (a) SRER and (b) JER. The SEE and the number of hourly samples (N) are shown for each site. Bin averages and ±1 standard deviation are shown (circles and error bars) for bin widths of 0.025 m$^3$/m$^3$ for each estimate.

**Fig. 6:** Scatterplots of the spatially-averaged change in soil moisture (m$^3$/m$^3$) derived from CRSSoil moisture spatial variability as a function of the spatially-averaged distributed sensor
network ($\theta_{SN}$, top) and the CRNS method ($\Delta \theta_{CRNS}$, bottom) for (a, c) SRER and (b, d) JER. Bin averages and ±1 standard deviation are shown (circles and error bars) for bin widths of 0.015 m$^3$/m$^3$ at SRER and 0.025 m$^3$/m$^3$ at JER. Regressions for the relations of σ with $<\theta>$ are valid for the entire dataset.

**Fig. 7:** Scatterplots of the spatially-averaged change in soil moisture (m$^3$/m$^3$) derived from CRNS method ($\Delta \theta_{CRNS}$) and the application of the water balance ($\Delta \theta_{WB}$) at (a) SRER and (b) JER. The SEE and the number of event samples (N) are shown for each site.

**Fig. 7**

- Change in soil moisture ($\Delta \theta_{SN}$) at depths of 5, 15 and 30 cm at the JER for the five large events (‘Selected Events’) and the remaining cases (‘Other Events’). Horizontal lines are the CRSTime-averaged CRNS measurement depths averaged over the corresponding cases (black is Selected Events, gray is Other Events).
- Standard deviation of 3.8 cm) and Other Events (gray; standard deviation of 6.5 cm).

**Fig. 8:** Comparison of cumulative $f_{CRS}$ and measured water balance fluxes ($P$ and $ET$) during study period. CRSCRNS estimates of infiltration ($I$), outflow ($O$) and leakage ($L$) are either depicted as cumulative fluxes ($O = ET + L$) or as total amounts during the study period ($I$ and $L$) as arrows in the soil water balance box of depth $z^*$. Shaded regions indicate the summer seasons (July-September). The horizontal line represents $f_{CRS} = 0$.

**Fig. 9:** Soil moisture spatial variability as a function of the spatially-averaged distributed sensor network ($\theta_{SN}$, top) and the CRS method ($\theta_{CRS}$, bottom) for (a, c) SRER and (b, d) JER. Black symbols represent the standard deviation (σ) and gray symbols depict the coefficient of variation (CV). Bin averages and ±1 standard deviation are shown (circles and error bars) for bin widths of...
0.015 m³/m³ at SRER and 0.025 m³/m³ at JER. Regressions for the relations of \( \sigma \) and \( CV \) with \(<\theta>\) are valid for the entire dataset.

**Fig. 10:** Evapotranspiration relation with the spatially-averaged distributed sensor network (\( \theta_{SN} \), top) and the \( CRSCRNS \) method (\( \theta_{CRS},\theta_{CRNS} \), bottom) for (a, c) SRER and (b, d) JER. Bin averages and ±1 standard deviation are shown (circles and error bars) for bin widths of 0.015 m³/m³ at SRER and 0.025 m³/m³ at JER. Regressions for the relations of \( ET \) with \(<\theta>\) are valid for the entire dataset.

**Fig. 11:** Evapotranspiration relation with the soil moisture standard deviation (\( \sigma \), left) and the coefficient of variation (\( CV \), right) for (a, b) SRER and (c, d) JER. Bin averages and ±1 standard deviation are shown (circles and error bars) for bin widths of 0.33 mm/day. Solid lines represent predicted analytical relationships (not regressions).

Table Captions

Table 1: Watershed and precipitation characteristics at the SRER and JER sites. Precipitation values are long-term averages (1923-2014 at SRER and 1915-2006 at JER) for annual and seasonal quantities, defined as fall (October-December), winter (January-March), spring (April-June) and summer (July-September).

Table 2: Energy balance closure at SRER and JER using 30-min net radiation ($R_n$), ground ($G$), latent ($\lambda E$) and sensible ($H$) heat fluxes. The parameters $m$ and $b$ are the slope and intercept in the relation $\lambda E + H = m(R_n - G) + b$, while the ratio of the sum of ($\lambda E + H$) to the sum of ($R_n - G$) is a measure of how much available energy is accounted for in the turbulent fluxes.

Table 3: Statistical comparisons of CRS method with distributed sensor network and water balance estimates based on the Standard Error of Estimates, $\text{SEE} = \sqrt{\frac{\sum (\theta_{SN} - \theta_{CRS})^2}{N}}$, Root Mean Square Error, $\text{RMSE} = \sqrt{\frac{\sum (\theta'_{CRS} - \theta_{CRS})^2}{N}}$, where $\theta'_{CRS}$ is Soil properties at SRER and JER. Soil moisture values correspond to conditions during the CRNS calibration dates (February 13, 2013 at SRER and February 10, 2013 at JER) for the predicted value of $\theta_{CRS}$ based on gravimetric sampling at 18 locations with six depths ($\theta_G$), CRNS ($\theta_{CRNS}$) and the best fit line with sensor network ($\theta_{SN}$), Bias, $B = \frac{\theta_{CRS}}{\theta_{SN}}$, and Correlation Coefficient, $CC = \frac{\sum_{i=1}^{N} (\theta_{CRS,i} - \theta_{CRS}) (\theta_{SN,i} - \theta_{SN})}{\left[ \sum_{i=1}^{N} (\theta_{CRS,i} - \theta_{CRS})^2 \right]^{0.5} \left[ \sum_{i=1}^{N} (\theta_{SN,i} - \theta_{SN})^2 \right]^{0.5}}$, where $\theta_{CRS}$ and $\theta_{SN}$ represent the mean soil moisture for each measurement method expressed as volumetric soil moisture using the soil
bulk density ($\rho_b$) and $N$-soil porosity ($\phi$) of the number of samples. Values in parentheses for JER indicate metrics when large rainfall events are excluded. Mean values of $\theta_G$, $\rho_b$ and $\phi$ are shown along with the $\pm$ 1 standard deviations. Particle size distributions were obtained from soil auger sampling of the top 45 cm at 20 locations at each site (Anderson, 2013). Mean values of percent clay, silt, sand and gravel are shown along with the $\pm$ 1 standard deviations.

Table 4: Statistical comparisons of CRNS method with distributed sensor network and water balance estimates based on the Standard Error of Estimates (SEE), Root Mean Square Error (RMSE), Bias (B), and Correlation Coefficient (CC), described in Vivoni et al. (2008b). Values in parentheses for JER indicate metrics when large rainfall events are excluded.

Table 5: Total water flux estimates from daily CRNS and distributed sensor measurements during study period at the SRER and JER sites. $P$ is from rain gauge measurements in both cases. $L$ in CRNS is computed as $O - ET$ where $ET$ is from EC method, while $L$ in sensor estimates is calculated from solving the water balance.

Table 5: Regression parameters for the relations of the spatial variability of soil moisture ($\sigma$ and CV) and $<\theta>$ at the SRER and JER sites along with the RMSE of the regressions.

Table 6: Regression parameters for the relations of evapotranspiration and soil moisture ($\theta_{SN}$ and $\theta_{CRS}$) CRNS at the SRER and JER sites along with the RMSE of the regressions. $\theta_h = 0$ in all cases.
