Abstract

Observations of climate are often available on very different spatial scales from observations of the natural environments and resources that are affected by climate change. In order to help bridge the gap between these scales using modelling, a new dataset of daily meteorological variables was created at 1 km resolution over Great Britain for the years 1961-2012, by interpolating coarser resolution climate data and including the effect of local topography. These variables were used to calculate atmospheric evaporative demand (AED) at the same spatial and temporal resolution. Two functions that represent AED were chosen: one is a standard form of Potential Evapotranspiration (PET) and the other is a derivative of it used by hydrologists that includes the effect of water intercepted by the canopy (PETI). Temporal trends in these functions were calculated, with PET found to be increasing in all regions, and at an overall rate of 0.021±0.021 mm d\(^{-1}\) decade\(^{-1}\) in Great Britain, while PETI was found to be increasing at a rate 0.023±0.023 mm d\(^{-1}\) decade\(^{-1}\) in England (0.028±0.025 mm d\(^{-1}\) decade\(^{-1}\) in the English Lowlands), but not increasing at a statistically significant rate in Scotland or Wales. The trends were found to vary by season, with spring PET increasing by 0.043±0.019 mm d\(^{-1}\) decade\(^{-1}\) (0.038±0.018 mm d\(^{-1}\) decade\(^{-1}\) when the interception correction is included) in Great Britain, while there is no statistically significant trend in other seasons. The trends were attributed analytically to trends in the climate variables; the overall positive trend was predominantly driven by rising air temperature, although rising specific humidity had a negative effect on the trend. Increasing downward short- and longwave radiation made an overall positive contribution to the PET trend, while the 10 m wind speed had a negative effect. The trend in spring PET was particularly strong due to a strong increase in spring downward shortwave radiation.
1 Introduction

There are many studies showing the ways in which our living environment is changing over time: changing global temperatures (IPCC, 2013), radiation (Wild, 2009) and wind speeds (McVicar et al., 2012) can have significant impacts on ecosystems and human life (IPCC, 2014a). While there are overall global trends, the impacts can vary between regions (IPCC, 2014b). In the UK, wildlife surveys of both flora (Wood et al., 2015; Evans et al., 2008) and fauna (Pocock et al., 2015) show a shift in patterns and timing (Thackeray et al., 2010). In addition, the UK natural resources of freshwater (Watts et al., 2015), soils (Reynolds et al., 2013; Bellamy et al., 2005) and vegetation (Berry et al., 2002; Hickling et al., 2006; Norton et al., 2012) are changing. The UK is experiencing new environmental stresses on the land and water systems through changes in temperature and river flows (Crooks and Kay, 2015; Watts et al., 2015; Hannaford, 2015), which is part of a widespread global pattern of temperature increase and circulation changes (Watts et al., 2015).

To explain these changes in terms of climate drivers, there are several gridded meteorological datasets available at global and regional scales. Global datasets can be based on observations – for example the 0.5° resolution Climate Research Unit time series 3.21 (CRU TS 3.21) data (Jones and Harris, 2013; Harris et al., 2014) – while some are based on global meteorological reanalyses bias-corrected to observations – for example the WATCH Forcing Data (WFD, 0.5°; Weedon et al. (2011)), the WATCH Forcing Data methodology applied to ERA-Interim reanalysis product (WFDEI, 0.5°; Weedon et al. (2014)) and the Princeton Global Meteorological Forcing Dataset (1°; Sheffield et al. (2006)). At the regional scale in Great Britain (GB), there are datasets that are derived directly from observations – for example the Met Office Rainfall and Evaporation Calculation System (MORECS) dataset at 40 km resolution (Thompson et al., 1981; Hough and Jones, 1997) and the UKCP09 observed climate data at 5 km resolution (Jenkins et al., 2008).

However, while regional observations of carbon, methane and water emissions from the land (Baldocchi et al., 1996), the vegetation cover (Morton et al., 2011) and soil properties (FAO/IAISA/ISRIC/ISS-CAS/JRC, 2012) are typically made at the finer landscape scale of 100 m to 1000 m, most of these long-term gridded meteorological datasets are only available at a relatively coarse resolution of a few tens of km. These spatial scales may not be representative of the climate experienced by the flora and fauna being studied, and it has also been shown that input resolution can have a strong effect on the performance of hydrological
models (Kay et al., 2015). In addition, the coarse temporal resolution of some datasets, for example the monthly CRU TS 3.21 data (Harris et al., 2014; Jones and Harris, 2013), can miss important sub-monthly extremes.

Regional studies are important to identify drivers and impacts of changing meteorology that may or may not be reflected in trends in global means. For example, in Canada (Vincent et al., 2015) and Europe (Fleig et al., 2015), high resolution meteorological data have been used to identify the impacts of changing circulation patterns, while in Australia wind speed data have been used to quantify the effects of global stilling in the region (McVicar et al., 2008). While there are datasets available at finer spatial and temporal resolutions for the UK (such as UKCP09 (Jenkins et al., 2008)), these often do not provide all the variables needed to identify the impacts of changing climate.

To address this, we have created a meteorological dataset for Great Britain at 1 km resolution (Robinson et al., 2015a). It is derived from the observation-based MORECS dataset (Thompson et al., 1981; Hough and Jones, 1997), and then downscaled using information about topography. This is augmented by an independent precipitation dataset – Gridded Estimates of daily and monthly Areal Rainfall for the United Kingdom (CEH-GEAR; Tanguy et al. (2014); Keller et al. (2015)) – along with variables from two global datasets – WFD and CRU TS 3.21 – to produce a comprehensive, observation-based, daily meteorological dataset at 1 km × 1 km spatial resolution.

In order to understand the effect of meteorology on the water cycle, a key variable in hydrological modelling is the atmospheric evaporative demand (AED), which is determined by meteorological variables (Kay et al., 2013). It has been shown that water-resource and hydrological model results are largely driven by how this property is defined and used (Haddeland et al., 2011). The AED can be expressed in several ways, for instance the evaporation from a wet surface, from a well-watered but dry uniform vegetated cover, or from a hypothetical well-watered but dry version of the actual vegetation. Metrics such as the Palmer Drought Severity Index (PDSI; Palmer (1965)) use potential evapotranspiration (PET) as an input while many hydrological models such as Climate and Land use Scenario Simulation in Catchments (CLASSIC; Crooks and Naden (2007)) or Grid-to-Grid (G2G; Bell et al. (2009)), use as input a distinct form of the PET which includes the intercepted water from rainfall (this is described later in the text) which we hereby name PETI. While hydrological models can make use of high resolution topographic information and precipitation datasets, they are often
driven with PET calculated at a coarser resolution (Bell et al., 2011; Bell et al., 2012; Kay et al., 2015). Therefore, we have also created a dataset consisting of estimates of PET and PETI, which can be used to run high-resolution hydrological models (Robinson et al., 2015b).

Other regional studies have created gridded estimates of AED in Austria (Haslinger and Bartsch, 2016) and Australia (Donohue et al., 2010). Regional studies of trends in AED have seen varied results, with increasing AED seen in Romania (Paltineanu et al., 2012), Serbia (Gocic and Trajkovic, 2013), Spain (Vicente-Serrano et al., 2014), some regions of China (Li and Zhou, 2014) and Iran (Azizzadeh and Javan, 2015; Hosseinzadeh Talaee et al., 2013; Tabari et al., 2012), decreasing AED in north east India (Jhajharia et al., 2012) and regions in China (Yin et al., 2009; Song, 2010; Shan et al., 2015; Zhao et al., 2015; Zhang et al., 2015; Lu et al., 2016) and regional variability in Australia (Donohue et al., 2010) and China (Li et al., 2015).

In order to understand this variability, it is important to quantify the relative contributions of the changing meteorological variables to trends in AED and regional studies often find different drivers of changing AED (see McVicar et al. (2012) for a review). Relative humidity has been shown to drive AED in the Canary Islands (Vicente-Serrano et al., 2016), wind speed and air temperature were shown to have nearly equal but opposite effects in Australia (Donohue et al., 2010), while in China sunshine hours (Li et al., 2015), wind speed (Yin et al., 2009) or a combination of the two (Lu et al., 2016) have been shown to drive trends. Rudd and Kay (2015) investigated projected changes in PET using a regional climate model, but little has been done to investigate historical trends of AED in the UK.

The objectives of this paper are (i) to evaluate the trends in key meteorological variables in Great Britain over the years 1961-2012; (ii) to evaluate the AED in Great Britain over the same time period; (iii) to investigate the effect of including interception in the formulation of PET called PETI; (iv) to evaluate trends in PET over the time period of interest; and (v) to attribute the trends in PET to trends in meteorological variables. To address these objectives, the paper is structured as follows. Section 2 presents the calculation of the meteorological variables. Section 3 presents the calculation of PET and PETI from the meteorological variables and assesses the difference between PET and PETI. In Section 4 the trends in annual means of the meteorological variables and AED are calculated and the trends in PET are attributed to trends in meteorological variables. In Section 5 the results are discussed and conclusions are presented in Section 6.
2 Calculation of meteorological variables

The meteorological variables included in this new dataset (Robinson et al., 2015a) are daily mean values of air temperature, specific humidity, wind speed, downward longwave (LW) and shortwave (SW) radiation, precipitation and air pressure, plus daily temperature range (Table 1). These variables are important drivers of near-surface conditions, and, for instance, are the full set of variables required to drive the JULES land surface model (LSM) (Best et al., 2011; Clark et al., 2011), as well as other LSMs.

The data were derived primarily from MORECS, which is a long-term gridded dataset starting in 1961 and updated to the present (Thompson et al., 1981; Hough and Jones, 1997). It interpolates five variables from synoptic stations (daily mean values of air temperature, vapour pressure and wind speed, daily hours of bright sunshine and daily total precipitation) to a 40 km × 40 km resolution grid aligned with the Ordnance Survey National Grid. There are currently 270 stations reporting in real time, while a further 170 report the daily readings on a monthly basis, but numbers have varied throughout the run. The algorithm interpolates a varying number of stations (up to nine) for each square, depending on data availability (Hough and Jones, 1997). The interpolation is such that the value in each grid square is the effective measurement of a station positioned at the centre of the square and at the grid square mean elevation, averaged from 00:00 GMT to 00:00 GMT the next day. MORECS is a consistent, quality-controlled time series, which accounts for changing station coverage. The MORECS variables were used to derive the air temperature, specific humidity, wind speed, downward LW and SW radiation and air pressure in the new dataset. The WFD and CRU TS 3.21 datasets were used for surface air pressure and daily temperature range respectively, as they could not be calculated from MORECS. Additionally precipitation was obtained from the CEH-GEAR data, which is a product directly interpolated to 1 km from the station data (Keller et al., 2015).

The spatial coverage of the dataset was determined by the spatial coverage of MORECS, which covers the majority of Great Britain, but excludes some coastal regions and islands at the 1 km scale. For most of these points, the interpolation was extended from the nearest MORECS squares, but some outlying islands (in particular Shetland and the Scilly Isles) were excluded when the entire island was further than 40 km from the nearest MORECS square.
2.1 Air temperature

Air temperature, $T_a$ (K), was derived from the MORECS air temperature. The MORECS air temperature was reduced to mean sea level, using a lapse rate of -0.006 K m$^{-1}$ (Hough and Jones, 1997). A bicubic spline was used to interpolate from 40 km resolution to 1 km resolution, then the temperatures were adjusted to the elevation of each 1 km square using the same lapse rate. The 1 km resolution elevation data used were aggregated from the Integrated Hydrological Digital Terrain Model (IHDTM) – a 50 m resolution digital terrain model (Morris and Flavin, 1990).

2.2 Specific humidity

Specific humidity, $q_a$ (kg kg$^{-1}$), was derived from the MORECS vapour pressure, which was first reduced to mean sea level, using a lapse rate of -0.025 % m$^{-1}$ (Thompson et al., 1981). The actual lapse rate of humidity will, in general, vary according to atmospheric conditions. However, calculating this would require more detailed information than is available in the input data used. Any method of calculating the variation of specific humidity with height will involve several assumptions, but the method used here is well-established and is used by the Met Office in calculating MORECS (Thompson et al., 1981). The value of the vapour pressure lapse rate is chosen to keep relative humidity constant with altitude, rather than assuming that the specific humidity itself is constant.

A bicubic spline was used to interpolate vapour pressure to 1 km resolution then the values were adjusted to the 1 km resolution elevation using the IHDTM elevations. Finally the specific humidity was calculated, using

$$q_a = \frac{ee}{p_* - (1-\epsilon)e},$$

(1)

where $e$ is the vapour pressure (Pa) and $\epsilon = 0.622$ is the mass ratio of water to dry air (Gill, 1982). The air pressure, $p_*$, in this calculation was assumed to have a constant value of 100000 Pa because this was prescribed in the computer code. It would be better to use a varying air pressure, as calculated in Section 2.8, but this makes a negligible difference (of a few percent) to the calculated specific humidity and a constant $p_*$ was retained.
2.3 Downward shortwave radiation

Downward SW radiation, $S_d$ (W m$^{-2}$), was derived from the MORECS hours of bright sunshine (defined as the total number of hours in a day for which solar irradiation exceeds 120 W m$^{-2}$ (WMO, 2013)). The value calculated is the mean SW radiation over 24 hours. The sunshine hours were used to calculate the cloud cover factor, $C_f = n/N$, where $n$ is the number of hours of bright sunshine in a day, and $N$ is the total number of hours between sunrise and sunset (Mathews et al., 2011). The cloud cover factor was interpolated to 1 km resolution using a bicubic spline. The downward SW solar radiation for a horizontal plane at the Earth’s surface was then calculated using the solar angle equations of Iqbal (1983) and a form of the Angstrom-Prescott equation which relates hours of bright sunshine to solar irradiance (Ångström, 1918; Prescott, 1940), with empirical coefficients calculated by Cowley (1978). They vary spatially and seasonally and effectively account for reduction of irradiance with increasing solar zenith angle, as well as implicitly accounting for spatially- and seasonally-varying aerosol effects. However, they do not vary interannually and thus do not explicitly include long-term trends in aerosol concentration.

The downward SW radiation was then corrected for the average inclination and aspect of the surface, assuming that only the direct beam radiation is a function of the inclination and that the diffuse radiation is homogeneous. It was also assumed that the cloud cover is the dominant factor in determining the diffuse fraction (Muneer and Munawwar, 2006). The aspect and inclination were calculated using the IHDTM elevation at 50 m resolution, following the method of Horn (1981), and were then aggregated to 1 km resolution. The top of atmosphere flux for horizontal and inclined surfaces was calculated following Allen et al. (2006) and the ratio used to scale the direct beam radiation.

2.4 Downward longwave radiation

Downward LW radiation, $L_d$ (W m$^{-2}$), was derived from the 1 km resolution air temperature (Sect. 2.1), vapour pressure (Sect. 2.2) and cloud cover factor (Sect. 2.3). The downward LW radiation for clear sky conditions was calculated as a function of air temperature and precipitable water using the method of Dilley and O’Brien (1998), with precipitable water calculated from air temperature and humidity following Prata (1996). The additional component due to cloud cover was calculated using the equations of Kimball et al. (1982), assuming a constant cloud base height of 1000 m.
2.5 Wind speed

The wind speed at a height of 10 m, $u_{10}$ (m s$^{-1}$), was derived from the MORECS 10 m wind speed, which were interpolated to 1 km resolution using a bicubic spline and adjusted for topography using a 1 km resolution dataset of mean wind speeds produced by the UK Energy Technology Support Unit (ETSU) (Newton and Burch, 1985; Burch and Ravenscroft, 1992). This used Numerical Objective Analysis Boundary Layer (NOABL) methodology and station wind measurements over the period 1975-84 to produce a map of mean wind speed over the UK. To calculate the topographic correction, the ETSU wind speed was aggregated to 40 km resolution, then the difference between each 1 km value and the corresponding 40 km mean found. This difference was added to the interpolated daily wind speed. In cases where this would result in a negative wind speed, the wind speed was set to zero.

2.6 Precipitation

Precipitation rate, $P$ (kg m$^{-2}$ s$^{-1}$), is taken from the daily CEH-GEAR dataset (Tanguy et al., 2014; Keller et al., 2015), scaled to the appropriate units. The CEH-GEAR methodology uses natural neighbour interpolation (Gold, 1989) to interpolate synoptic station data to a 1 km resolution gridded daily dataset of the estimated precipitation in 24 hours between 09:00 GMT and 09:00 GMT the next day.

2.7 Daily temperature range

Daily temperature range (DTR), $D_T$ (K), was obtained from the CRU TS 3.21 monthly mean daily temperature range estimates on a 0.5° latitude × 0.5° longitude grid, which is interpolated from monthly climate observations (Harris et al., 2014; Jones and Harris, 2013). There is no standard way to correct DTR for elevation, so these data were reprojected to the 1 km grid with no interpolation and the monthly mean used to populate the daily values in each month. Although DTR is not required in the calculation of AED, it is a required input of the JULES LSM, in order to run at sub-daily timestep.

2.8 Surface air pressure

Surface air pressure, $p_*$ (Pa), was derived from the WFD, an observation-corrected reanalysis product, which provides 3 hourly meteorological data for 1958-2001 on a 0.5° latitude × 0.5° longitude resolution grid (Weedon et al., 2011). Mean monthly values of WFD surface air
Pressure and air temperature were calculated for each 0.5° grid box over the years 1961-2001. These were reprojected to the 1 km grid with no interpolation, then the lapse rate of air temperature (Sect. 2.1) used to calculate the integral of the hypsometric equation, in order to obtain the air pressure at the elevation of each 1 km grid (Shuttleworth, 2012). The mean monthly values were used to populate the daily values in the full dataset, thus the surface air pressure in the new dataset does not vary interannually, but does vary seasonally. This is reasonable as the trend in surface air pressure in the WFD is negligible (Weedon et al., 2011).

### 2.9 Spatial and seasonal patterns of meteorological variables

Long-term mean values of the meteorological variables were calculated for each 1 km square over the whole dataset (1961-2012) (Fig. 1). Four sub-regions of interest were defined (Fig. 2); three of these regions correspond to nations (England, Wales and Scotland), while the fourth is the ‘English lowlands’, a subset of England, covering south-central and south-east England, East Anglia and the East Midlands (Folland et al., 2015). Mean-monthly climatologies (Fig. 3) were calculated over the whole of Great Britain (GB), and over these four regions of interest.

The maps clearly show the effect of topography on the variables (Fig. 1), with an inverse correlation between elevation and temperature, specific humidity, downward LW radiation and surface air pressure and a positive correlation with wind speed. The precipitation has an east-west gradient due to prevailing weather systems and orography. The fine-scale structure of the downward SW radiation is due to the aspect and elevation of each grid cell, with more spatial variability in areas with more varying terrain. As no topographic correction has been applied to DTR, it varies only on a larger spatial scale. Although specific humidity is inversely proportional to elevation, relative humidity is not, as the saturated specific humidity will also be inversely proportional to elevation due to the decrease in temperature with height.

The mean-monthly climatologies (Fig. 3) demonstrate the differences between the regions, with Scotland generally having lower temperatures and more precipitation than the average, and England (particularly the English lowlands) being warmer and drier.

### 2.10 Validation of meteorology

The precipitation dataset, CEH-GEAR, has previously been validated against observations (Keller et al., 2015). Other studies discuss the uncertainties in the CRU TS 3.21 daily temperature range data (Harris et al., 2014) and WFDEI air pressure data (Weedon et al., 2014).
For the other variables, the MORECS data set is ultimately derived from the synoptic stations around the UK which represent most of the available observed meteorological data. The only way to validate the gridded meteorology presented here is to compare it to independently observed data, which are available at a few sites where meteorological measurement stations are located. Here we carry out a validation exercise with data from four sites from the UK, which have meteorological measurements available for between 5 and 10 years. Details of the sites and data are in Appendix A. Fig. 4 shows the comparison of data set air temperature with the observed air temperature at each of the four sites. This shows a strong correlation ($r^2$ between 0.94 and 0.97) between the data set and the observations. Fig. 5 shows the mean-monthly climatology calculated from both the data set and from the observations (only for times for which observations were available) and demonstrates that the data set successfully captures the seasonal cycle. This has been repeated for downward SW radiation and for an estimate of the mixing ratio of water vapour, 10 m wind speed and surface air pressure (Appendix A). The air temperature, downward SW radiation and mixing ratio all have high correlations and represent the seasonal cycle well. The wind speed is overestimated by the derived data set at two sites, which is likely to be due to land cover effects. The modelling which produced the ETSU dataset uses topography but not land cover (Burch and Ravenscroft, 1992; Newton and Burch, 1985), so at sites with tall vegetation the wind speed is likely to be less than the modelled value. The air pressure has a low correlation because the data set contains a mean-monthly climatological value. However, the mean bias is low and the RMSE is small, confirming that it is reasonable to use a climatological value in place of daily data.

3 Calculation of potential evapotranspiration (PET)

There are several ways to assess the evaporative demand of the atmosphere. Pan evaporation can be modelled using the Pen-Pan model, or open-water evaporation can be modelled with the Penman equation. However, neither of these account for the fact that in general the evaporation is occurring from a vegetated surface. A widely used model is the Penman-Monteith PET, $E_P$ (mm d$^{-1}$, equivalent to kg m$^{-2}$ d$^{-1}$), which is a physically-based formulation of the AED of the atmosphere (Monteith, 1965). It provides an estimate of AED dependent on the atmospheric conditions but allowing for the fact that that the water is evaporating through the surface of leaves and thus the resistance is higher. It is calculated from the daily meteorological variables using the equation
\[ E_p = \frac{t_d^{\Delta A + \frac{c_p \rho_a}{r_a} (q_s - q_a)}}{\Delta + \gamma (1 + \frac{t_d}{r_a})} , \]

where \( t_d = 86400 \) s \( \text{d}^{-1} \) is the length of a day, \( \lambda = 2.5 \times 10^6 \) J kg\(^{-1} \) is the latent heat of evaporation, \( q_s \) is saturated specific humidity (kg kg\(^{-1} \)), \( \Delta \) is the gradient of saturated specific humidity with respect to temperature (kg kg\(^{-1} \) K\(^{-1} \)), \( A \) is the available energy (W m\(^2\)), \( c_p = 1010 \) J kg\(^{-1} \) K\(^{-1} \) is the specific heat capacity of air, \( \rho_a \) is the density of air (kg m\(^{-3} \)), \( q_a \) is specific humidity (kg kg\(^{-1} \)), \( \gamma = 0.004 \) K\(^{-1} \) is the psychrometric constant, \( r_s \) is stomatal resistance (s m\(^{-1} \)) and \( r_a \) is aerodynamic resistance (s m\(^{-1} \)) (Stewart, 1989).

The saturated specific humidity, \( q_s \) (kg kg\(^{-1} \)), is calculated from saturated vapour pressure, \( e_s \) (Pa), using Eq. (1). The saturated vapour pressure is calculated using an empirical fit to air temperature, \( e_s = p_s e^{\sum a_i (1 - T_s T_a)^i} \),

where \( p_s = 101325 \) Pa is the steam point pressure, \( T_s = 373.15 \) K is the steam point temperature and \( a = (13.3185, -1.9760, -0.6445, -0.1299) \) are empirical coefficients (Richards, 1971).

The derivative of the saturated specific humidity with respect to temperature, \( \Delta \) (kg kg\(^{-1} \) K\(^{-1} \)), is therefore

\[ \Delta = \frac{T_s}{T_a^2} \frac{p_s q_s}{p_s - (1 - e) e_s} \sum a_i (1 - T_s T_a)^{-i} . \]

The available energy, \( A \) (W m\(^2\)), is the energy balance of the surface,

\[ A = R_n - G , \]

where \( R_n \) is the net radiation (W m\(^2\)) and \( G \) is the soil heat flux (W m\(^2\)). The net soil heat flux is negligible at the daily timescale (Allen et al., 1998), so the available energy is equal to the net radiation, such that

\[ A = (1 - \alpha) S_d + \varepsilon (L_d - \sigma T_s^4) . \]

where \( \sigma \) is the Stefan-Boltzmann constant, \( \alpha \) is the albedo and \( \varepsilon \) the emissivity of the surface and \( T_s \) is the surface temperature (Shuttleworth, 2012). For this study the surface temperature is approximated by using the air temperature, \( T_a \).

The air density, \( \rho_a \) (kg m\(^{-3} \)), is a function of air pressure and temperature,
\[ \rho_a = \frac{p_s}{r_a}, \]  
\[ \text{(7)} \]

where \( r = 287.05 \text{ J kg}^{-1} \text{ K}^{-1} \) is the gas constant of air.

The stomatal and aerodynamic resistances are strongly dependent on land cover due to differences in roughness length and physiological constraints on transpiration of different vegetation types. In addition, the albedo and emissivity are also dependent on the land cover.

In order to investigate the effect of meteorology on AED, as distinct from land use effects, the PET was calculated for a single land cover type over the whole of the domain. If necessary, this can be adjusted to give an estimate of PET specific to the local land cover, for example using regression relationships (Crooks and Naden, 2007). As a standard, the Food and Agriculture Organization of the United Nations (FAO) calculate reference crop evaporation for a hypothetical reference crop, which corresponds to a well-watered grass (Allen et al., 1998).

Following this, the PET in the current study was calculated for a reference crop of 0.12 m height, with constant stomatal resistance, \( r_s = 70.0 \text{ s m}^{-1} \), an albedo of 0.23 and emissivity of 0.92 over the whole of Great Britain. This study therefore neglects the effect of land-use on evaporation, which could be investigated in future by calculating PET for different land surface types, with different coverage for each year of the dataset.

Following Allen et al. (1998), the aerodynamic resistance, \( r_a (\text{s m}^{-1}) \), is a function of the 10 m wind speed

\[ r_a = \frac{278}{u_{10}}. \]  
\[ \text{(8)} \]

Thus the PET is a function of six of the meteorological variables: air temperature, specific humidity, downward LW and SW radiation, wind speed and surface air pressure.

To explore the role of the different meteorological variables in the AED, it is helpful to split the radiative component (the first part of the numerator in Equation 2) from the wind component (the second part). Formally, this is defined as follows (Doorenbos, 1977):

The radiative component, \( E_{PR} \),

\[ E_{PR} = t_d \frac{\Delta A}{\Delta + \gamma (1 + \frac{\Delta}{\tau_a})}, \]  
\[ \text{(9)} \]

and the aerodynamic component, \( E_{PA} \),

\[ E_{PA} = \frac{c_{rp} q_s - q_a}{\Delta + \gamma (1 + \frac{\Delta}{\tau_a})}, \]  
\[ \text{(10)} \]
such that $E_t = E_{PR} + E_{PA}$.

### 3.1 Potential evapotranspiration with interception (PETI)

When rain falls, water is intercepted by the canopy. The evaporation of this water is not constrained by stomatal resistance but is subject to the same aerodynamic resistance as transpiration (Shuttleworth, 2012). At the same time, transpiration is inhibited in a wet canopy. Suppression of transpiration is well observed both by comparing eddy-covariance fluxes and observations of sap flow (Kume et al., 2006; Moors, 2012), and by observing stomatal and photosynthesis response to wetting (Ishibashi and Terashima, 1995). For plants which have at least some of their stomata on the upper surface of the leaves, this can be due to water directly blocking the stomata. However, in GB most plants have stomata only on the underside of the leaves, so the transpiration is inhibited by other mechanisms.

Physically, the suppression may simply be due to the fact that energy is used in evaporating the intercepted water, so less is available for transpiration (Bosveld and Bouten, 2003) or that the increased humidity of the air, due to evaporation of intercepted water, causes the stomata to close (Lange et al., 1971). It may also be due to the presence of water causing stomatal closure through physiological reactions, which can be observed even when the stomata are on the underside of a leaf and the water is lying on the upper side (Ishibashi and Terashima, 1995).

In the short term after a rain event, potential water losses due to evaporation may be underestimated if only potential transpiration is calculated, and therefore overall rates underestimated. As transpiration is inhibited over the wet fraction of the canopy (Ward and Robinson, 2000), the PET over a grid box will be a linear combination of the potential interception and potential transpiration, each weighted by the fraction of the canopy that is wet or dry. This can be accounted for by introducing an interception term to the calculation of PET, giving PETI. This is modelled as an interception store, which is (partially) filled by rainfall, proportionally inhibiting the transpiration. As the interception store dries, the relative contribution of interception is decreased and the transpiration increases. This correction is applied on days with precipitation, while on days without precipitation, the potential is equal to the PET defined in Eq. 2. Although an unconventional definition of PET, a similar interception correction is applied to the PET provided at 40 km resolution by MORECS (Thompson et al., 1981) which is used widely by hydrologists.
This method implicitly assumes that the water is liquid, however snow lying on the canopy will also inhibit transpiration, and will be depleted by melting as well as by sublimation. The rates may be slower, and the snow may stay on the canopy for longer than one day. However, the difference of accounting for canopy snow as distinct from canopy water will have a small effect on large-scale averages, as the number of lying snow days in GB is relatively low, and they occur during winter when the PET is very small.

The PETI is a weighted sum of the PET, \( E_P \), (as calculated in Eq 2.) and potential interception, \( E_I \), which is calculated by substituting zero stomatal resistance, \( r_s=0 \text{ s m}^{-1} \), into Eq. 2. To calculate the relative proportions of interception and transpiration, it is assumed that the wet fraction of the canopy is proportional to the amount of water in the interception store. The interception store, \( S_I \) (kg m\(^{-2}\)), decreases through the day according to an exponential dry down (Rutter et al., 1971), such that

\[
S_I(t) = S_0 e^{-\frac{E_I}{S_{tot}} t}, \quad (11)
\]

where \( E_I \) is the potential interception, \( S_{tot} \) is the total capacity of the interception store (kg m\(^{-2}\)), \( S_0 \) is the precipitation that is intercepted by the canopy (kg m\(^{-2}\)) and \( t \) is the time (in days) since a rain event. The total capacity of the interception store is calculated following Best et al. (2011), such that

\[
S_{tot} = 0.5 + 0.05\Lambda, \quad (12)
\]

where \( \Lambda \) is the leaf area index (LAI); for the FAO standard grass land cover the LAI is 2.88 (Allen et al., 1998). The fraction of precipitation intercepted by the canopy is found also following Best et al. (2011), assuming that precipitation lasts for an average of 3 hours.

The wet fraction of the canopy, \( C_{wet} \), is proportional to the store size, such that

\[
C_{wet}(t) = \frac{S(t)}{S_{tot}}. \quad (13)
\]

The total PETI is the sum of the interception from the wet canopy and the transpiration from the dry canopy,

\[
E_{PI}(t) = E_I C_{wet}(t) + E_P \left(1 - C_{wet}(t)\right). \quad (14)
\]

This is integrated over one day to find the total PETI, \( E_{PI} \) (mm d\(^{-1}\)), to be
\[ E_{PI} = S_0 \left( 1 - e^{-\frac{E_I}{S_{tot}}} \right) + E_p \left( 1 - \frac{S_0}{E_I} \left( 1 - e^{-\frac{E_I}{S_{tot}}} \right) \right). \]

(15)

The PETI is a function of the same six meteorological variables as the PET, plus the precipitation.

### 3.2 Spatial and seasonal patterns of PET and PETI

Both PET and PETI have a distinct gradient from low in the north-west to high in the south-east, and they are both inversely proportional to the elevation (Fig. 6), reflecting the spatial patterns of the meteorological variables. The PETI is 8% higher than the PET overall but this difference is larger in the north and west, where precipitation rates, and therefore interception, are higher (Fig. 6). In Scotland, the higher interception and lower AED mean that this increase is a larger proportion of the total, with the mean PETI being 11% larger than the PET (in some areas the difference is more than 25%). In the English lowlands the difference is smaller, at 6%, but this is a more water limited region where hydrological modelling can be sensitive to even relatively small adjustments to PET (Kay et al., 2013).

The seasonal climatology of both PET and PETI follow the meteorology (Fig. 7), with high values in the summer and low in the winter. Although the relative difference peaks in winter, the absolute difference between PET and PETI is bimodal, with a peak in March and a smaller peak in October (September in Scotland) (Fig. 7), because in winter the overall AED is low, while in summer the amount of precipitation is low, so the interception correction is small. The seasonal cycle of PET is driven predominantly by the radiative component, which has a much stronger seasonality than the aerodynamic component (Fig. 8).

On a monthly or annual timescale, the ratio of PET to precipitation is an indicator of the wet- or dryness of a region (Oldekop, 1911; Andréassian et al., 2016). Low values of PET relative to precipitation indicate wet regions, where evaporation is demand-limited, while high values indicate dry, water-limited regions. In the wetter regions (Scotland, Wales) mean-monthly PET and PETI (Fig. 7) are on average lower than the mean-monthly precipitation (Fig. 3) throughout the year, while in drier regions (England, English lowlands) the mean PET and PETI are higher than the precipitation for much of the summer, highlighting the regions’ susceptibility to hydrological drought (Folland et al., 2015).
4 Decadal trends

4.1 Meteorological Variables

Annual means of the meteorological variables (Fig. 9) and the PET and PETI (Fig. 10) were calculated for each region. The trends in these annual means were calculated using linear regression; the significance (P value) and 95% confidence intervals (CI) of the slope are calculated specifically allowing for the non-zero lag-1 autocorrelation, to account for possible correlations between adjacent data points (Zwiers and von Storch, 1995; von Storch and Zwiers, 1999). In addition, seasonal means were calculated, with the four seasons defined to be Winter (December-February), Spring (March-May), Summer (June-August) and Autumn (September-November), and trends in these means were also found. The trends can be seen in Table 2.

The trends in the annual and seasonal means for all regions are plotted in Fig. 11; trends that are statistically significant at the 5% level are plotted with solid error bars, those that are not significant are plotted with dashed lines. The analysis was repeated for each pixel in the 1 km resolution dataset; maps of these rates of change can be seen in Appendix B.

There was a statistically significant trend in air temperature in all regions (except in winter), which agrees with recent trends in the Hadley Centre Central England Temperature (HadCET) dataset (Parker and Horton, 2005) and in temperature records for Scotland (Jenkins et al., 2008) as well as in the CRUTEM4 dataset (Jones et al., 2012). An increase in winter precipitation in Scotland is seen in the current dataset, which leads to a statistically significant increase in the annual mean precipitation of GB. However, all other regions and seasons have no statistically significant trends in precipitation. Long term observations show that there has been little trend in annual precipitation, but a change in seasonality with wetting winters and drying summers since records began, although with little change over the past 50 years (Jenkins et al., 2008).

The statistically significant decline in wind speed in all regions is consistent with the results of McVicar et al. (2012) and Vautard et al. (2010), who report decreasing wind speeds in the northern hemisphere over the late 20th century.

4.2 Potential Evapotranspiration

The trends of the meteorological variables are interesting in their own right. But for hydrology, it is the impact that the trends have on evaporation that matters and that depends on their combination, which can be expressed through PET.
The regional trends of annual mean PET and PETI can be seen in Table 2, and the trends in the annual and seasonal means of PET, PETI, and the radiative and aerodynamic components of PET are plotted in Fig. 12 for all regions. Maps of the trends can be seen in Appendix B. The trend in the radiative component of PET is positive over the whole of GB. However, the trend in the aerodynamic component varies; for much of Wales, Scotland and northern England, it is not significant, or is slightly negative, while in south-east England and north-west Scotland it is positive. This leads to a positive trend in PET over much of GB, but no significant trend in southern Scotland and northern England. There is a statistically significant increase in annual PET in all regions except Wales; the GB trend (0.021±0.021 mm d⁻¹ decade⁻¹) is equivalent to an increase of 0.11±0.11 mm d⁻¹ (8.3±8.1 % of the long term mean) over the whole dataset. Increases in PETI are only statistically significant in England (0.023±0.023 mm d⁻¹ decade⁻¹) and English lowlands (0.028±0.025 mm d⁻¹ decade⁻¹), where the increases over the whole dataset are 0.12±0.12 mm d⁻¹ (8.0±8.0 % of the long term mean) and 0.15±0.13 mm d⁻¹ (9.7±8.8 % of the long term mean) respectively. There is a difference in trend between different seasons. In winter, summer and autumn there are no statistically significant trends in PET or PETI, other than the English lowlands in autumn, but the spring is markedly different, with very significant trends (P<0.0005) in all regions. The GB spring trends in PET (0.043±0.019 mm d⁻¹ decade⁻¹) and PETI (0.038±0.018 mm d⁻¹ decade⁻¹) are equivalent to an increase of 0.22±0.10 mm d⁻¹ (13.8±6.2 % of the long-term spring mean) and 0.20±0.09 mm d⁻¹ (11.2±5.3 % of the long-term spring mean) over the length of the dataset respectively. The radiative component of PET has similarly significant trends in spring, while the aerodynamic component has no significant trends in any season (Fig. 12), indicating that the trend in PET is due to the increasing radiative component.

There are few studies of long-term trends in AED in the UK. MORECS provides an estimate of Penman-Monteith PET with interception correction calculated directly from the 40 km resolution meteorological data (Hough and Jones, 1997; Thompson et al., 1981), and increases can be seen over the dataset (Rodda and Marsh, 2011). But as the PET and PETI in the current dataset are ultimately calculated using the same meteorological data (albeit by different methods), it is not unexpected that similar trends should be seen. Site-based studies suggest an increase over recent decades (Burt and Shahgedanova, 1998; Crane and Hudson, 1997), but it is difficult to separate climate-driven trends from local land-use trends. A global review paper (McVicar et al., 2012) identified a trend of decreasing AED in the northern hemisphere, driven by decreasing wind speeds, however they also reported significant local variations on trends in
pan evaporation, including the increasing trend observed by Stanhill and Möller (2008) at a site in England after 1968. Matsouka et al. (2011) identified a statistically significant increase in PET in several regions of the globe, including southern England, between 1983 and 2008, attributing it predominantly to an increase in the radiative component of PET, due to global brightening. However, these results were obtained using reanalysis data, which is limited in its ability to capture trends in wind speed. This limitation has been documented in both northern (Pryor et al., 2009) and southern (McVicar et al., 2008) hemispheres.

Regional changes in actual evaporative losses can be estimated indirectly using regional precipitation and runoff or river flow. Using a combination of observations and modelling, Marsh and Dixon (2012) identified an increase in evaporative losses in Great Britain from 1961-2011. Hannaford and Buys (2012) note seasonal and regional differences in trends in observed river flow, suggesting that decreasing spring flows in the English lowlands are indicative of increasing AED. However, changing evaporative losses can also be due to changing supply through precipitation, so it is important to formally attribute the trends in PET to changing climate, in order to understand changing evapotranspiration.

4.3 Attribution of trends in potential evapotranspiration

In order to attribute changes in PET to changes in climate, the rate of change of PET, \( \frac{dE_P}{dt} \) (mm d\(^{-1}\) decade\(^{-1}\)), can be calculated as a function of the rate of change of each variable (Roderick et al., 2007),

\[
\frac{dE_P}{dt} = \frac{dE_P}{dT_a} \frac{dT_a}{dt} + \frac{dE_P}{dq_a} \frac{dq_a}{dt} + \frac{dE_P}{du_{10}} \frac{du_{10}}{dt} + \frac{dE_P}{dL_d} \frac{dL_d}{dt} + \frac{dE_P}{dS_d} \frac{dS_d}{dt}. \quad (16)
\]

Note that we exclude the surface air pressure, because this dataset uses a mean-monthly climatology as the interannual variability of air pressure is negligible. The derivative of the PET with respect to each of the meteorological variables can be found analytically (Appendix C). The derivatives are calculated from the daily meteorological data at 1 km resolution. Substituting the slopes of the linear regressions of the gridded annual means (Appendix B) for the rate of change of each variable with time, and the overall time-average of the derivatives of PET with respect to the meteorological variables, the contribution of each variable to the rate of change of PET can be calculated at 1 km resolution. These are then averaged over the regions of interest. The same can also be applied to the radiative and aerodynamic components independently.
Note that this can also be applied to the regional means of the derivatives of PET and the trends in the meteorological variables. The results are compared in Table 3 and the two approaches are consistent. For the regional analysis, we also quote the 95% CI. However, for the gridded values, there is such high spatial coherence that combining the 95% CI over the region results in unreasonably constrained results. We therefore use the more conservative CI obtained from the regional analysis. Also note that this method assumes that the rate of change of the variables with respect to time is constant over the whole dataset (and thus the product of the means is equal to the mean of the products), and indeed this is how it is often applied (Donohue et al., 2010; Lu et al., 2016). The effect of this assumption was investigated by repeating the analysis with seasonal trends and means, but this makes negligible difference to the results.

Fig. 13 shows the contribution of each meteorological variable to the rate of change of the annual mean PET and to the radiative and aerodynamic components and compares the total attributed trend to that obtained by linear regression. The percentage contribution is in Table 4, calculated as a fraction of the fitted trend. The final columns shows the total attributed trend as a percentage of the fitted trend, to demonstrate the success of the attribution at recovering the fitted trends. For the PET trend and for the trend in the radiative component, these values generally sum to the linear regression to within a few percent. However, for the aerodynamic component, the fitted trend is very small (an order of magnitude smaller than the PET and radiative component trends), and much smaller than the statistical uncertainty. This means that there can be a large and/or negative percentage difference between the attributed and fitted trends, even when the absolute difference is negligible.

The largest overall contribution to the rate of change of PET comes from increasing air temperature, which has the effect of increasing the aerodynamic component (as it makes the air more able to hold water), but it decreases the radiative component (due to increasing outgoing LW radiation). However, the decrease due to increasing specific humidity largely cancels this increase in the aerodynamic component. Overall the next largest increases are caused by increasing downward SW radiation, particularly in the English regions in the spring, as it increases the radiative component of PET. However, in Scotland and Wales, the increasing downward LW radiation is also important. Finally, the decreasing wind speed has the effect of increasing the radiative component, but decreasing the aerodynamic component, so overall it tends to cause a decrease in PET.
Since the increasing air temperature and downward LW and SW radiation have the effect of increasing PET, but the increasing specific humidity and decreasing wind speed tend to decrease it, then the overall trend is positive, but smaller than the trend due to air temperature alone.

5 Discussion

These high resolution datasets provide insight into the effect of the changing climate of Great Britain on AED over the past five decades. There have been significant climatic trends in the UK since 1961; in particular rising air temperature and specific humidity, decreasing wind speed and decreasing cloudiness. Although some are positive and some negative, these meteorological trends combine to give statistically significant trends in PET.

Wind speeds have decreased more significantly in the west than the east, and show a consistent decrease across seasons. Contrary to Donohue et al. (2010) and McVicar et al. (2012), this study finds that the change in wind speed of the late 20th and early 21st centuries has had a negligible influence on PET over the period of study. However, the previous studies were concerned with open-water Penman evaporation, which has a simpler (proportional) dependence on wind speed than the Penman-Monteith PET considered here (Schymanski and Or, 2015).

The air temperature trend in this study of 0.21±0.15 K decade\(^{-1}\) in GB is consistent with observed global and regional trends (Hartmann et al., 2013; Jenkins et al., 2008). The temperature trend is responsible for a large contribution to the trend in PET, although the large negative contribution from the specific humidity (as well as a small negative contribution from wind speed) means that the overall trend is smaller than the temperature trend alone.

Although the contribution is smaller than that of air temperature, the trends in LW radiation in these datasets contribute to between 15% and 28% of the trends in PET and between 27% and 46% of the trends in the radiative component. Observations of LW radiation are often uncertain, but the trend in this dataset, although small, is consistent with observed trends (Wang and Liang, 2009), as well as with trends in the WFDEI bias-corrected reanalysis product (Weedon et al., 2014).

Increasing solar radiation has been shown to increase spring and annual AED, contributing to between 18% and 50% of the fitted trend in annual PET, and to between 43% and 53% of the fitted trend in spring PET. Two main mechanisms can be responsible for changing solar radiation – changing cloud cover and changing aerosol concentrations. Changing aerosol
emissions have been shown to have had a significant effect on solar radiation in the 20th century. In Europe, global dimming due to increased aerosol concentrations peaked around 1980, followed by global brightening as aerosol concentrations decreased (Wild, 2009). Observations of changing continental runoff and river flow in Europe over the 20th century have been attributed to changing aerosol concentrations, via their effect on solar radiation, and thus AED (Gedney et al., 2014).

In this study we use the duration of bright sunshine to calculate the solar radiation, using empirical coefficients which do not vary with year, so aerosol effects are not explicitly included. The coefficients used in this study to convert sunshine hours to radiation fluxes were empirically derived in 1978; the derivation used data from the decade 1966-75, as this period was identified to be before reductions in aerosol emissions had begun to significantly alter observed solar radiation (Cowley, 1978). Despite this, the trend in SW radiation in the current dataset from 1979 onwards (1.4±1.4 W m^-2 decade^-1) is consistent, within uncertainties, with that seen over GB in the WFDEI data (0.9±1.1 W m^-2 decade^-1), which is bias-corrected to observations and includes explicit aerosol effects (Weedon et al., 2014).

It has been suggested that aerosol effects also implicitly affect sunshine duration since in polluted areas, there will be fewer hours above the official ‘sunshine hours’ threshold of 120 W m^-2 (Helmes and Jaenicke, 1986). Several regional studies have shown trends in sunshine hours that are consistent with the periods of dimming and brightening across the globe (eg Liley, 2009; Sanchez-Lorenzo et al., 2009; Sanchez-Lorenzo et al., 2008; Stanhill and Cohen, 2005), and several have attempted to quantify the relative contribution of trends in cloud cover and aerosol loading (e.g. Sanchez-Lorenzo and Wild (2012) in Switzerland, see Sanchez-Romero et al. (2014) for a review). Therefore, it may be that some of the brightening trend seen in the current dataset is due to the implicit signal of aerosol trends in the MORECS sunshine duration, although this is likely to be small compared to the effects of changing cloud cover.

The trends in the MORECS sunshine duration used in this study are consistent with changing weather patterns which may be attributed to the Atlantic Multidecadal Oscillation (AMO). The AMO has been shown to cause a decrease in spring precipitation (and therefore cloud cover) in northern Europe over recent decades (Sutton and Dong, 2012), and the trend in MORECS sunshine hours is dominated by an increase in the spring mean. This has also been seen in Europe-wide sunshine hours data (Sanchez-Lorenzo et al., 2008). On the other hand, the effect of changing aerosols on sunshine hours is expected to be largest in the winter (Sanchez-Lorenzo...
et al., 2008). However, it would not be possible to directly identify either of these effects on the sunshine duration without access to longer data records.

The inclusion of explicit aerosol effects in the coefficients of the Angstrom-Prescott equation would be expected to reduce the positive trend in AED in the first two decades of the dataset, and increase it after 1980. Gedney et al. (2014) attribute a decrease in European solar radiation of 10 W m\(^{-2}\) between the periods 1901-10 and 1974-80, and an increase of 4 W m\(^{-2}\) from 1974-84 to 1990-99 to changing aerosol contributions. Applying these trends to the current dataset, with a turning point at 1980, would double the overall increase in solar radiation in Great Britain, which would lead to a 40% increase in the overall trend in PET. So, if this effect were to be included, it would confirm the results found in this paper.

Trends in temperature and cloud cover in the UK are expected to continue into the coming decades, with precipitation expected to increase in the winter but decrease in the summer (Murphy et al., 2009). Therefore it is likely that AED will increase, increasing water stress in the summer when precipitation is lower and potentially affecting water resources, agriculture and biodiversity. This has been demonstrated for southern England and Wales by Rudd and Kay (2015), who calculated present and future PET using high-resolution RCM output and include the effects of CO\(_2\) on stomatal opening.

The current study is concerned only with the effects of changing climate on AED and has assumed a constant bulk canopy resistance throughout. However, plants are expected to react to increased CO\(_2\) in the atmosphere by closing stomata and limiting the exchange of gases, including water (Kruijt et al., 2008), and observed changes in runoff have been attributed to this effect (Gedney et al., 2006; Gedney et al., 2014). It is possible that the resulting change of canopy resistance could partially offset the increased atmospheric demand (Rudd and Kay, 2015) and may impact runoff (Gedney et al., 2006; Prudhomme et al., 2014), but further studies would be required to quantify this.

6 Conclusion

This paper has presented a unique high-resolution observation-based dataset of meteorological variables and AED in Great Britain since 1961. Key trends in the meteorological variables are (i) increasing air temperature and specific humidity, consistent with global temperature trends; (ii) increasing solar radiation, particularly in the spring, consistent with changes in aerosol emissions and weather patterns in recent decades; (iii) decreasing wind speed, consistent with observations of global stilling; and (iv) increasing precipitation, driven by increasing winter
precipitation in Scotland. The meteorological variables were used to evaluate AED in Great Britain via calculation of PET and PETI. It has been demonstrated that including the interception component in the calculation of PETI gives a mean estimate that is overall 8% larger than PET alone, with strong seasonality and spatial variation of the difference. PET was found to be increasing by 0.021±0.021 mm d⁻¹ decade⁻¹ over the study period. With the interception component included, the trend in PETI is weaker, and over GB is not significant at the 5% level. The trend in PET was analytically attributed to the trends in the meteorological variables, and it was found that the dominant effect was that increasing air temperature was driving increasing PET. This is largely compensated by the associated increase in specific humidity, as the water cycle is intensified under climate change and by decreasing wind speed. However, the PET increase is also driven by increasing solar radiation, particularly in the spring.

In addition to providing meteorological data for analysis, the meteorological variables provided are sufficient to run LSMs and hydrological models. The high spatial (1 km) and temporal (daily) resolution will allow this dataset to be used to study the effects of climate on physical and biological systems at a range of scales, from local to national.

**Data Access**

The data can be downloaded from the Environmental Information Platform at the Centre for Ecology & Hydrology. The meteorological variables can be found at https://catalogue.ceh.ac.uk/documents/80887755-1426-4dab-a4a6-250919d5020c, while the PET and PETI can be accessed at https://catalogue.ceh.ac.uk/documents/d329f4d6-95ba-4134-b77a-a377e0755653.

**Author contribution**

EB, JF and DBC designed the study. JF, ACR, DBC and ELR developed code to create meteorological data. ELR created the PET and PETI. ELR and EB analysed trends. ELR, EB, ACR and DBC wrote the manuscript.

**Acknowledgements**

The meteorological variables presented are based largely on GB meteorological data under licence from the Met Office, and those organisations contributing to this national dataset (including the Met Office, Environment Agency, Scottish Environment Protection Agency (SEPA) and Natural Resources Wales) are gratefully acknowledged. The CRU TS 3.21 daily
temperature range data were created by the University of East Anglia Climatic Research Unit, and the WFD air pressure data were created as part of the EU FP6 project WATCH (Contract 036946). Collection of flux data was funded by EU FP4 EuroFlux (Griffin Forest); EU FP5 CarboEuroFlux (Griffin Forest); EU FP5 GreenGrass (Easter Bush); EU FP6 CarboEuropeIP (Alice Holt, Griffin Forest, Auchencorth Moss, Easter Bush); EU FP6 IMECC (Griffin Forest); the Forestry Commission (Alice Holt); the Natural Environment Research Council, UK (Auchencorth Moss, Easter Bush).

Thanks to Nicola Gedney and Graham Weedon for useful discussions. This work was partially funded by the Natural Environment Research Council in the Changing Water Cycle programme: NERC Reference: NE/I006087/1.
Appendix A: Data validation

Meteorological data were downloaded from the European Fluxes Database Cluster (http://gaia.agraria.unitus.it) for four sites positioned around Great Britain. Two were woodland sites (Alice Holt (Wilkinson et al., 2012; Heinemeyer et al., 2012) and Griffin Forest (Clement, 2003)), while two had grass and crop cover (Auchencorth Moss (Billett et al., 2004) and Easter Bush (Gilmanov et al., 2007; Soussana et al., 2007)). Table A1 gives details of the data used. The data are provided as half-hourly measurements, which were used to create daily means, where full daily data coverage was available. The daily means of the observed data were compared to the daily data from the grid square containing the site and the Pearson correlation ($r^2$), mean bias and root mean square error (RMSE) were calculated. For each site, monthly means were calculated where the full month had available data, then a climatology calculated from available months. The same values were calculated from the relevant grid squares, using only time periods for which observed data were available.

Fig. A1 shows the comparison of the data set downward SW radiation against daily mean air temperature observed at the four sites. Fig. A2 shows the mean-monthly climatology of the daily values. The observed values of the mixing ratio of water vapour in air were compared with values calculated from the meteorological dataset, using the equation

$$r_w = q_a \left( \frac{m_a}{m_w} \right)$$

where $m_a$ is the molecular mass of dry air and $m_w$ is the molecular mass of water. The comparisons are shown in Figs. A3 and A4.

Table A2 shows the $r^2$, mean bias and RMSE for each of the variables included in the validation exercise. The correlations indicate a good relationship between the dataset variables and the independent observations at the sites, while the mean-monthly climatologies demonstrate that the data represent the seasonal cycle well.

Appendix B: Trend maps

Fig. B1 shows the rate of change of each of the meteorological variables at the 1 km resolution, while Fig. B2 shows the rate of change of the PET, PETI, and the two components of PET at the same resolution. This shows that the regional trends are consistent with spatial variation and are not dominated by individual extreme points.

Appendix C: Derivatives of PET
The wind speed affects the PET through the aerodynamic resistance. The derivative with respect to wind speed is

$$\frac{\partial E_P}{\partial u_{10}} = \frac{(\Delta+\gamma)E_{PA} - \gamma \frac{E_{PR}}{R_n}}{u_{10}(\Delta+\gamma (1+\frac{r_s}{r_a}))}. \quad (C1)$$

The downward LW and SW radiation affect PET through the net radiation, and the derivatives are

$$\frac{\partial E_P}{\partial L_d} = E_{PR} \frac{\varepsilon}{R_n}. \quad (C2)$$

$$\frac{\partial E_P}{\partial S_d} = E_{PR} \frac{(1-\alpha)}{R_n}. \quad (C3)$$

The derivative of PET with respect to specific humidity is

$$\frac{\partial E_P}{\partial q_a} = \frac{E_{PA}}{q_a - q_s}. \quad (C4)$$

The air temperature affects PET through the saturated specific humidity and its derivative, the net radiation and the air density, so that the derivative of PET with respect to air temperature is

$$\frac{\partial E_P}{\partial T_a} = E_{PR} \left[ \frac{\gamma(1+\frac{T_s}{T_a})}{T_a^2(\Delta+\gamma(1+\frac{r_s}{r_a}))} \left[ T_{sp} \left( \sum_{i=1}^{4} i a_i T_r^{i-1} - \frac{2(1-\varepsilon) \frac{\Sigma_{i=1}^{4} i a_i T_r^{i-1} q_s}{\varepsilon}}{2T_a} - 2T_a \right) \right] - \frac{4\varepsilon T_a^4}{R_n} \right] + E_{PA} \left[ \frac{\Delta}{q_s-q} - \frac{1}{T_a} - \frac{\Delta}{T_a^2(\Delta+\gamma(1+\frac{r_s}{r_a}))} \left[ T_{sp} \left( \sum_{i=1}^{4} i a_i T_r^{i-1} - \frac{2(1-\varepsilon) \frac{\Sigma_{i=1}^{4} i a_i T_r^{i-1} q_s}{\varepsilon}}{2T_a} - 2T_a \right) \right] \right]. \quad (C5)$$

uncertainty range from the regional analysis is used in Fig. 13.

Table 3. Contributions to the rate of change of PET and its radiative and aerodynamic components. For each variable, the first column shows the contribution calculated using regional averages, along with the associated 95% CI. The second column shows the contribution calculated at 1 km resolution, then averaged over each region. The uncertainty on this value is difficult to calculate as the pixels are highly spatially correlated, so the uncertainty range from the regional analysis is used in Fig. 13.

Figure 1. Means of the meteorological variables over the years 1961-2012. The variables are:

a) 1.2 m air temperature, b) 1.2 m specific humidity, c) precipitation, d) 10 m wind speed, e) downward LW radiation, f) downward SW radiation, g) surface air pressure, h) daily air temperature range.
Figure 2. The regions used to calculate the area means. The English lowlands are a sub-region of England. England, Scotland and Wales together form the fifth region, Great Britain.
Figure 3. Mean monthly climatology of meteorological variables, a) 1.2 m air temperature, b) 1.2 m specific humidity, c) precipitation, d) 10 m wind speed, e) downward LW radiation, f) downward SW radiation, g) surface air pressure, h) daily air temperature range, for five different regions of Great Britain, calculated over the years 1961-2012.
Figure 4. Plot of data set air temperature against daily mean air temperature at four sites. The dashed line shows the one to one line, while the solid line shows the linear regression, the equation of which is shown in the lower right of each plot, along with the $r^2$ value, the mean bias and the RMSE. The sites are a) Alice Holt; b) Griffin Forest; c) Auchencorth Moss; d) Easter Bush.
Figure 5. Mean monthly climatology of the dataset (blue, solid lines) and observed air temperatures (black, dashed lines), calculated for the period of observations. The thicker lines show the means, while the thinner lines show the standard errors on each measurement. Sites as in Fig. 4.
Figure 6. Mean a) PET, b) PETI, c) absolute difference between PETI and PET and d) relative difference calculated over the years 1961-2012.
Figure 7. Mean monthly climatology of a) PET, b) PETI, c) absolute difference between PETI and PET, d) relative difference, for five different regions of Great Britain, calculated over the years 1961-2012. Symbols as in Fig. 3.
Figure 8. Mean-monthly climatology of the a) radiative and b) aerodynamic components of the PET for five different regions of Great Britain, calculated over the years 1961-2012. Symbols as in Fig. 3.
Figure 9. Annual means of the meteorological variables, a) 1.2 m air temperature, b) 1.2 m specific humidity, c) precipitation, d) 10 m wind speed, e) downward LW radiation, f) downward SW radiation, g) daily air temperature range, over five regions of Great Britain. The solid black lines show the linear regression fit to the Great Britain annual means, while the grey strip shows the 95% CI of the same fit, assuming a non-zero lag-1 correlation coefficient. The equation of this fit is shown in the top right-hand corner of each plot.
Figure 10. Annual means of a) PET and b) PETI for five regions of Great Britain. Symbols as in Fig. 9.
Figure 11. Rate of change of annual and seasonal means of meteorological variables, a) 1.2 m air temperature, b) 1.2 m specific humidity, c) precipitation, d) 10 m wind speed, e) downward LW radiation, f) downward SW radiation, g) daily air temperature range, for five regions of Great Britain for the years 1961-2012. Error bars are the 95% CI calculated assuming a non-zero lag-1 correlation coefficient. Solid error bars indicate slopes that are statistically significant at the 5% level, dashed error bars indicate slopes that are not significant at the 5% level.
Figure 12. Rate of change of annual and seasonal means of a) PET, b) PETI, c) the radiative component of PET and d) the aerodynamic component of PET for five regions of Great Britain for the years 1961-2012. Symbols as in Fig. 11.
Figure 13. The contribution of the rate of change of each meteorological variable to the rate of change of a) PET, b) the radiative component and c) the aerodynamic component. The first five (four; three) bars are the contribution to the rate of change of annual mean PET from the rate of change of each of the variables, calculated per pixel, than averaged over each region. Each bar has an error bar showing the 95% CI on each value. Since the pixels are highly spatially correlated, we use the more conservative CI calculated by applying this analysis to the regional means. The next bar is the sum of the other bars and shows the attributed rate of change of annual mean PET. The final bar shows the slope and its associated CI obtained from the linear regression of the mean annual PET for each region.
Figure A1. Plot of data set downward SW radiation against daily mean downward SW radiation at four flux sites. Symbols and sites as in Fig. 4.
Figure A2. Mean monthly climatology of the dataset (blue, solid lines) and observed air temperatures (black, dashed lines), calculated for the period of observations. Symbols as in Fig. 5, sites as in Fig. 4.
Figure A3. Plot of mixing ratio calculated using dataset meteorology against daily mean observed mixing ratio at four sites. Symbols as in Fig. 4. The sites are a) Alice Holt and b) Griffin Forest.
Figure A4. Mean monthly climatology of the dataset (blue, solid lines) and observed mixing ratio (black, dashed lines), calculated for the period of observations. Symbols as in Fig. 5. Sites as in Fig. A3.
Figure B1. Rate of change of the meteorological variables, a) 1.2 m air temperature, b) 1.2 m specific humidity, c) precipitation, d) 10 m wind speed, e) downward LW radiation, f) downward SW radiation, g) surface air pressure, h) daily air temperature range over the period 1961-2012. Areas for which the trend was not significant are shown in grey.
Figure B2. Rate of change of a) PET, b) PETI, c) the radiative component of PET, d) the aerodynamic component of PET over the period 1961-2012. Areas for which the trend was not significant are shown in grey.
