Response to review

We would like to thank Dr. Anna Sikorska for her time and review and prof. Seibert for his further recommendations. Below we respond to the comments and indicate the changes made in the paper. The marked-up revised manuscript was added afterwards.

The reviewer’s comments

Comment (C):

1. p.5. l.6: change into "Data on annual maxima of daily discharges from more than 1800 river gauge stations (with catchment area ranging from 1.4 to 807,000 km²) were collected, together with information on terrain, land use and local catchments' climate."

2. p.9. l. 2: change "on the other hand" into "however"

3. p. 16 l. 19 remove "some" from supplementary data

4. p.18 l. 8: add comma before "especially" and remove "the performance is poor" from the sentence.

5. p.18 l. 34: add "even" before "better".

6. p.22 l. 16: remove "it"

7. p.22 l. 27: add "or floods" after floods of short duration, i.e.: "or floods in small catchments."

8. p.23 l. 1: "might still contain errors..."

9. p. 24 l. 12: change to "small and medium catchments..." if you use a threshold of 500km2.

10. p.25 l. 21: change into "increasing influence..."

11. Figure 8.: change "predicted" into "projected"

Response (R): All changes suggested by the reviewer we implemented as requested, except point 1, which was further modified according to our native speaker’s language check:

“Annual maxima of daily discharges from more than 1800 river gauges (stations with catchment areas ranging from 1.4 to 807,000 km²) were collected, together with information on terrain, land use and local climate.”

The editor’s comments

1. C: I have to say that the language partly could be improved and formulations could be more to the point. I list a few examples below. Please make sure to check your text once more very carefully to make sure formulations are as clear as possible and to avoid language mistakes (perhaps seek advice from a native speaker or professional copy-
editor).

R: We did a thorough re-read of the paper, making many corrections in the manuscript. We also employed the help of our colleague Antonia Sebastian from the USA to make a language check. She provided us with many corrections and suggestions for improvement, which we implemented in all sections.

2. C: Methods: “Some additional neighbouring basins were added for complete coverage of Europe except for the territory of the former Soviet Union. Only the outermost regions of Madeira, the Azores and the Canary Islands were omitted because they are outside the EURO-CORDEX climate model; notwithstanding, their river networks are very limited and therefore of little interest.”

No need to say that some rivers or of little interest (to which at least local people would disagree), just say that the islands in the Atlantic were excluded. These sentences also needs to be reformulated:

a. Do you mean upstream parts of ‘some’ basins were added or entirely additional basins? The formulation with some.. added .. except … is a bit difficult to follow.

b. I guess you excluded these islands entirely, but the sentence actually says only some regions on them were excluded, please clarify.

R: This paragraph was indeed unclear, therefore we rewrote it and now it reads the following:

“Discharge data from measurement stations were collected over a domain covering most of Europe (Fig. 2). The study area includes the entire continent, plus Cyprus as a European Union (EU) member, with two exceptions. Out of the territory of the former Soviet Union, only river basins that are at least partially located within the EU were included. Also, the outlying regions of Madeira, the Azores and the Canary Islands were omitted because they are outside the EURO-CORDEX climate model’s domain.”

3. C: Conclusions: “The accuracy at different ungauged locations however, as seen in Table 2, could differ.” Please do not refer to a table here, but formulate the sentence (or two) so that it is clear what results you are referring to.

R: The sentence was reformulated as follows:

“However, the accuracy at different ungauged locations varies to some degree. The best performance was found in Scandinavia, western Europe and the Danube basin, while the lowest was observed in southern Europe, especially in the Iberian Peninsula”

4. C: “The advantages of our approach is that it is has low computational expense, it is explicit and flexible.”

Grammatical mistake :… are that. Furthermore, please be more specific, what do you mean by explicit and flexible in the context of this method.

R: The paragraph was rewritten so that the expressions ‘explicit’ and ‘flexible’ are placed together with their explanations:

“There are several advantages of our approach. It has low computational expense, The method is also flexible as its configuration could be easily modified, and the model can be used even if not all variables for a given location are available. At the same time it allows to perform sensitivity analysis of different variables on extreme discharges, as
well as easily incorporate changes in climate or land use over time. It relies purely on the statistical distributions and statistical dependence of catchment descriptors, without any empirical modifiers or clustering typical for other statistical methods. The model also has a graphical nature, which makes its formulation explicit.”
Estimating extreme river discharges in Europe through a Bayesian Network

Abstract. Large-scale hydrological modelling of flood hazard requires adequate extreme discharge data. In practise, models based on physics are applied alongside those utilizing only statistical analysis. The former requires enormous computational power, while the latter are mostly limited in accuracy and spatial coverage. In this paper we introduce an alternate, statistical approach based on Bayesian Networks (BN), a graphical model for dependent random variables. We use a non-parametric BN to describe the joint distribution of extreme discharges in European rivers and variables describing the geographical characteristics of their catchments. Data on Annual maxima of daily discharges from more than 1800 river gauges (stations with catchment areas ranging from 1.4 to 807,000 km²) were collected, together with information on terrain, land use and local climate of catchments (ranging from 1.4 to 807,000 km²) that drain to those locations. The (conditional) correlations between the variables are modelled through copulas, with the dependency structure defined in the network. The results show that using this method, mean annual maxima and return periods of discharges could be estimated with an accuracy similar to existing studies using physical models for Europe, and better than a comparable global statistical method. Performance of the model varies slightly between regions of Europe, but is consistent between different time periods, and is not affected by a split-sample validation. Though discharge prediction under climate change is not the main scope of this paper, as an example of application of our method, the BN was applied to a large domain covering all sizes of rivers in the continent, both for present and future climate. Results show large substantial variation in the influence of climate change on river discharges, as well as large differences between emission scenarios. The method could be used to provide quick estimates of extreme discharges at any location for the purpose of obtaining input information for hydraulic modelling.

Keywords. hydrology; catchments; floods; copulas; climate change; return periods; flood risk

1 Introduction

There is currently substantial concern in Europe about increasing flood risk linked mainly to climate change. Available studies (Whitfield 2012, Feyen et al. 2012, Alfieri et al. 2015) predict that the severity of floods will increase, due to changes in extreme precipitation and socio-economic development. Abundant availability of continental and global climate, land use and elevation data result in many studies analysing floods in the same large domain. However, the amount of hydrological observations at disposal is far from sufficient for comprehensive assessments of flood hazard. This is not only the result of an uneven network distribution of measurement stations, but also of the limited dissemination of data by national or local bodies responsible for their collection. High resolution historical measurements are critical for calculating At the same time, they are necessary to calculate accurate hydrological event scenarios for the purpose of delineating flood zones. Those scenarios are typically values of extreme river discharge or water level with a certain return period, i.e. the average interval of time between the occurrences of an event with the same magnitude. Such calculation additionally requires long data series, further narrowing the number of locations were such analysis can be performed. In effect, to conduct large-scale flood hazard studies, it is necessary to fill the gaps in measurements with modelled river flows. There are two main
groups of methods used to obtain discharge values in ungauged catchments, i.e. catchments for which no discharge measurements are available.

The first group of methods are rainfall-runoff models. They utilize physical equations describing processes such as infiltration, runoff, and retention in order to transform rainfall into river discharges. These models are typically used to model river flows at the catchment scale, although A large number of models have been used in smaller scales, though in recent years a few studies applied them on a continental or global scale. One series of publications (Dankers and Feyen 2008, Rojas et al. 2012, Alfieri et al. 2014 and others) presented calculations using LISFLOOD model. The simulation was set up for Europe with a 5-km resolution. Many different datasets of rainfall amount were analysed, including historical observations and future climate simulations, deriving daily discharge data for most of the continent.

Another group of studies (Ward et al. 2013, Winsemius et al. 2013) have introduced a global hydrological model GLOFRIS. This model has a much coarser resolution than the previous one—as its rainfall-runoff module uses a 0.5° grid (ca. 50–80 km resolution over Europe). All those studies used the modelling results to perform an extreme value analysis of modelled river discharges, and some also carried on with a flood hazard estimation. The main drawback of this approach is the computational expense, which necessitates a reduction in resolution (though it should be noted that the main driver—meteorological data—also have limited resolution). Additionally, only a limited number of rivers is included in the models. For instance, LISFLOOD-based studies used a threshold of 1000 km² catchment size, later reduced to 500 km². Meanwhile, while GLOFRIS was prepared only for rivers with Strahler order 6 or above, which is about only accounts for about a third of the river length included in the aforementioned European model.

The second group of approaches are statistical methods, of which a large variety exists. Several methods are based on the fact that catchments close to each other share many characteristics. River basins are therefore pooled into groups based on geographical proximity alone or also based on catchment size, climate data, terrain or soil type. However, the studies employing such techniques mostly covered a limited domain, typically single countries (Meigh et al. 1997, Salinas et al. 2013). The first global analysis was recently presented by Smith et al. (2015). The study applied regional frequency analysis (RFA) for all continents for the first time. Here, after clustering catchments based on size, climate type and average rainfall, a probability distribution of discharges is calculated for each region. Estimates of extreme discharges for a given ungauged catchment were derived by first assigning it to a proper region, and then using data on catchment size and rainfall together with region-specific coefficients to solve a simple regression equation is solved in order to obtain an estimate of the mean of annual maxima of discharges in the catchment. Lastly, a Generalized Extreme Value probability distribution with region-specific parameters is used to calculate return periods of discharges. Flood scenarios obtained through this method were used for a global flood hazard analysis through a LISFLOOD model by Sampson et al. (2015).

There are also several statistical methods that rely solely on the geographical characteristics of catchments to estimate discharges. Many of them are simple equations that can be easily applied to quickly solve practical problems in engineering,
such as estimating dike heights or calculating necessary channel or culvert capacity. Also, they are typically only applicable in small areas for which they were prepared. Usually, they are a variation of the “rational equation”, which states that river discharges can be calculated by multiplying the catchment area, by the rainfall intensity and runoff coefficient (Chow 1988, Sando 1998). The first two elements are used in virtually all methods, but the remaining element is either left out due to the difficulty of estimating it, or is derived from a model table of coefficients, or additional factors are added as proxies. For instance, Stachý and Fal (1986) developed an equation to calculate 100-year discharge in catchments above 50 km² in Poland which incorporates seven factors: catchment area, extreme rainfall (100-year return period), soil type, catchment slope, river slope, lake area and marsh area. However, it also requires incorporating an additional empirical coefficient for each physiogeographic region of the country, while different return periods than the default 100 years are obtained by multiplying discharge by a region-specific factor, similar to the RFA method. Another example is the preliminary flood risk assessment in Norway (Peereboom et al. 2011), which utilized a simple regression between catchment area and 500-year water level. An “envelope curve” approach was then applied, in which a curve is constructed in such a manner that it contains all (or almost all) observations. This concept was long used to make crude estimations of maximum possible floods, also on continental scale (e.g. Padi et al. 2011 applied it to Africa). Finally, some attempts have also been made to apply multiple linear regressions, also on global scale (Herold and Mouton 2010).

This paper presents a new statistical method to calculate extreme river discharges under present and future climate in Europe. It was devised as an alternative to existing physical and statistical models; its purpose was to provide boundary conditions for hydraulic modelling that could be used in a pan-European flood hazard analysis. The method is based on Bayesian Networks that combine probability theory and graph theory in order to build and operate a joint distribution. A Bayesian Network is used to analyse and represent the dependencies between different environmental variables, including river discharges. We present the quantification of the model based on a large dataset of river gauge observations and pan-European spatial datasets. The model shows good performance across regions of Europe at different time periods. We also present a comparison of this new approach with other methods, both physical and statistical. Lastly, we apply it over the entire domain to obtain a large database of extreme discharges, and analyse the influence of climate change on their return periods.

An early and preliminary variant of the method was originally reported in Paprotny and Morales Nápoles (2015). The Bayesian Network presented there is superseded by an improved version described herein. Also, the work is part of a bigger effort to create pan-European meteorological and hydrological hazard maps under “Risk analysis of infrastructure networks in response to extreme weather” (RAIN) project. This fact influenced the choice of the domain and input data, which is explained in the next section, although this does not limit the applicability of the method outside of the European domain.
2 Materials and methods

This section first gives an overview of the model’s framework and elements is given, and then proceeds with details on followed by a description of how the model was prepared, what datasets were used to build it, what are the underlying mathematical methods are, and how the model’s accuracy and utility was were assessed.

2.1 Workflow and outline of the method

The basic elements of the procedure to derive extreme discharge estimates through a Bayesian Network are presented in Fig. 1. The first step was to identifying available data on annual maxima (Q_{AMAX}) of daily river discharge (I), and also the catchments which contribute to locations where the measurements were made (section 2.2), i.e. gauged catchments (II). Then, several large-scale (pan-European or global) spatial datasets were compiled (III), providing information on the most important variables influencing extreme river flow behaviour (section 2.3), both for gauged and ungauged catchments (IV). The dependence between those variables and river discharges, were analysed through copulas and Bayesian Networks (section 2.4) (V). After extensive testing of different configurations, an optimal model was constructed (section 2.5) that had the highest performance in validation in terms of the underlying statistical model and prediction capability (sections 2.7 and 3.1) (VI). The output of the model are annual maxima of daily river discharges (VII), which were then fitted to a probability distribution in order to obtain return periods (section 2.6). After the method was ready, it was applied for all catchments (IV) in the domain to create a database of discharges (VIII). Using Frequency analysis, allowed then to obtain return periods of discharges under present and future climate in Europe (section 3.2) were obtained (IX). The accuracy of the Bayesian Network model was also contrasted with alternate methods (sections 3.1 and 4.1) (X).

2.2 River discharge data

Discharge data from measurements stations were collected over a domain covering most of Europe (Fig. 2). Because this research focuses on European Union (EU) countries, all river basins at least partially located in this group of states are included (including Cyprus, geographically part of Asia). Some additional neighbouring basins were added for complete coverage of Europe except for the territory of the former Soviet Union. Only the outermost regions of Madeira, the Azores and the Canary Islands were omitted because they are outside the EURO-CORDEX climate model; notwithstanding, their river networks are very limited and therefore of little interest. The study area includes the entire continent, plus Cyprus as a European Union (EU) member, with two exceptions. Out of the territory of the former Soviet Union, only river basins that are at least partially located within the EU were included. Also, the outlying regions of Madeira, the Azores and the Canary Islands were omitted because they are outside the EURO-CORDEX climate model’s domain.

In total, data series for 1841 stations were compiled, not including a few dozens of available stations whose tributaries could not be unequivocally identified and were therefore not included in excluded from the analysis. The data were collected from five sources, as follows:
- 1186 stations from the Global Runoff Data Centre (2016);
- 82 stations from the Norwegian Water Resources and Energy Directorate (2015);
- 284 stations from the Swedish Meteorological and Hydrological Institute (2016);
- 239 stations from Centro de Estudios Hidrográficos (2012);

The data collected were daily discharges observed between 1950 and 2013, though of primary interest were data up to 2005, since it was the maximum range of EURO-CORDEX climate models’ historical scenario runs. All datasets were quality-checked by the providers; only a few cases of misplaced decimals in daily series have been identified in the data after inspection. Daily discharges were transformed into annual maxima ($Q_{\text{AMAX}}$) for each calendar year, except for the last group of 50 stations, as Fal (2000) only reported the extreme and mean values. Total number of $Q_{\text{AMAX}}$ values for years 1950–2005 in the database was 74,757. The stations represent 37 countries and 439 different river basins (78% of the domain’s area of 5.67 million km$^2$). However, the south-eastern part of Europe is substantially underrepresented, with most stations concentrated in Scandinavia and western Europe. France has the highest number of $Q_{\text{AMAX}}$ values in the database (14%), followed closely by Spain, Sweden and the United Kingdom (UK), as can be seen in Table 1. On the other hand, the largest density of stations is in Switzerland, Austria and the UK. The catchments’ size spans from 1.4 to 807,000 km$^2$, with a biggest group of them being in the 100–1000 km$^2$ range.

Long data series, i.e. at least three full decades of uninterrupted data (1951–80, 1961–90 or 1971–2000) were available for 1125 stations. These observations were used to validate the accuracy of the model in estimating mean $Q_{\text{AMAX}}$ and return periods, while the complete database was used to quantify the Bayesian Network model.

### 2.3 Spatial datasets

Several large-scale spatial datasets were collected for this study, even though not all of them were used in the final set-up of the model. Nevertheless, all were useful for testing different configurations of the BN. The most important dataset was a map of the river network and catchments, which was derived from the pan-European CCM River and Catchment Database v2.1, or CCM2 (Vogt et al. 2007, de Jager and Vogt 2010). It was created by calculating flow direction and accumulation on a 100-m resolution digital elevation model (DEM), combined with land cover information, satellite imagery and national GIS databases. CCM2 was utilized to delimit the domain used in this paper. In total that area covers 831,125 river sections (almost 2 million km in length) in 70,638 river basins. Each river gauge station was connected with a corresponding river section in CCM2. Each river section belongs to one primary catchment, whose attributes includes the identifier of the next downstream catchment. Using this information, the whole tributary of a gauge station, or any other point in the domain, could be delimited. For each catchment, by employing GIS software, various statistics were calculated in GIS, based on other datasets described below. Additionally, a few indicators could be derived from this dataset alone: catchment area, river network density (total river length divided by catchment area) and catchment circularity (catchment area divided by
the area of a circle that has the same perimeter as the catchment), whereas others were derived using the datasets described below.

The next most relevant source of information are climate data, both historical and future projections. Two datasets for the former were analysed. E-OBS is a spatial interpolation of observations made by weather stations covering years 1950–2015 (Haylock et al. 2008), while ERA-Interim is a complete climate reanalysis for 1979–2015 (Dee et al. 2011). However, E-OBS has gaps in spatial coverage and includes few variables, whereas ERA-Interim has a relatively coarse resolution (0.75°). In effect, slightly better performance of the model was recorded using high-resolution control runs of a climate model under EURO-CORDEX framework (Jacob et al. 2014); the results of this analysis can be found in Supplement 2. EURO-CORDEX uses regional climate models (RCM) for Europe, where boundary conditions are obtained from global-scale general circulation models (GCM). In this work, we utilize simulations for the historical run (1950–2005) and two climate change scenarios (RCP 4.5 and RCP 8.5 for 2006–2100). The necessary variables (precipitation, snowmelt, and runoff) and resolution (0.11°) were included in a total of 14 model runs; of these, 8 model runs start in 1950. One of the model runs, one was made using GCM boundary conditions which came from a 12-member ensemble, and was therefore chosen as the model to develop and test the method.

This model run, which was selected to carry out this study, was made by the Climate Limited-area Modelling-Community utilizing EC-Earth general circulation model (run by ICHEC) with COSMO_4.8_clm17 regional climate model (Rockel et al. 2008), realization r12i1p1. This RCM also has relatively good model performance when estimating extreme precipitation in comparison with others (Kotlarski et al. 2014). No bias correction was performed, even though it is often considerable for extreme precipitation (Rojas et al. 2011). For the sake of simplicity and universality of the method, we opted to use all input data unaltered. However, as an additional check on the method’s performance, a different GCM-RCM combination was analysed, and the results were added to Supplement 2. From this dataset four variables were derived: total precipitation, snowmelt, near-surface temperature and total runoff. All data were daily values on a 0.11° rotated grid (spatial resolution of about 12 km).

Meteorological factors are the driving force behind floods, but more factors influence the runoff – terrain, land use and soils. Information on terrain was obtained from two digital elevation models. Most of the domain is available from EU-DEM, a dataset produced for the European Environment Agency. It was created by merging two sources of satellite altimetry data – Shuttle Radar Topography Mission (SRTM) and ASTER GDEM. It has a 25 m resolution and covers 39 countries (DHI GRAS 2014), including areas north of 60° N, missing from SRTM-only datasets. For Eastern Europe and some Atlantic islands which are not covered by EU-DEM, SRTM data were used instead (Farr et al. 2007). This model SRTM has a 3 arc second resolution (~100 meters over Europe) and has several versions available. The one used here is a void-filled derivate obtained from Viewfinder Panoramas (2014). Both datasets were resampled to a common 100 m grid matching the CCM2 dataset. The variables calculated from the DEMs included average elevation, average river slope and average catchment slope. The latter was derived either in the ways: by averaging all slopes in the DEM, or by calculating the slope S with the equation:
\[ S = \frac{H_{\text{max}} - H_{\text{min}}}{\sqrt{A}} \]  

where \( H_{\text{max}} \) is the maximum, and \( H_{\text{min}} \) the minimum, elevation in the catchment and \( A \) is the catchment area. Another variable, the time of concentration, which is a measure of water circulation speed in the catchment, was calculated based on Gericke and Smithers (2014). Finally, we tested terrain classification similar to one used in FLEX-Topo hydrological model (Savenije 2010). In this approach, all grid cells in the DEM are classified based on height-above-nearest-drainage (HAND), slope inclination and absolute elevation (Gharani et al. 2011, Gao et al. 2014). Three classes—wetlands, hillslopes and mountains—were calculated as percentage of total catchment area.

Land use statistics for catchments were mainly based on CORINE Land Cover (CLC), another dataset produced by the European Environment Agency (2014a). In this study, CLC 2000 edition, version 17 (12/2013) in raster format (100 m resolution) was used here. It includes 44 land cover classes with a minimum mapping unit of 25 ha and covers 39 countries. The main source material were Landsat 7 satellite images from years 1999–2001 (European Environment Agency 2007). Similarly to EU-DEM, the dataset does not cover some catchments in Eastern Europe and in a few other areas. Missing information was supplemented using the Global Land Cover 2000 dataset, produced by the Joint Research Centre using algorithmic processing of SPOT 4 satellite images (Bartalev et al. 2003). This product has a 30 arc second resolution and includes 22 land cover classes. The different classifications were synchronised to derive the area covered by forests, croplands (total and irrigated), marshes, lakes, glaciers, bare land and artificial surfaces. However, the data is only available for a single year for the whole domain, even though CLC was produced also for 2006, 2012 and, in some countries, for 1990. In contrast to terrain or soils, land use is dynamic and could influence the analysis for early time periods. Yet, some historical land-use reconstructions and projections (e. g. Klein Goldewijk et al. 2011) do not have the necessary resolution or thematic coverage for use in this analysis. Therefore, a fixed values of land use percentages were used for all years, including the future climate change scenarios.

Last but not least, data on soil properties were analysed. Occurrence of peat, unconsolidated and Eolian deposits, average water content and soil texture were derived from European Soil Database v2.0 (Panagos et al. 2012), developed at 1:1,000,000 scale, and Harmonized World Soil Database v1.2 (FAO/IIASA/ISRIC/ISS-CAS/JRC 2012), available at 30 arc second resolution. Also, soil sealing (i.e. area covered by artificial impervious surfaces) was obtained from Revised Soil Sealing 2006, a dataset based on satellite imagery with a 100 m resolution (European Environment Agency 2014b). Additionally, grain-size structure of the soil (gravel, sand, silt, clay) was calculated from SoilGrids1km database (Hengl et al. 2014).

### 2.4 Bayesian Networks

As noted in the introduction, Bayesian Networks (BN) are graphical, probabilistic models (Pearl 1988, Kurowicka and Cooke 2006). They have several advantages when compared to other methods, for the application described in this paper. For one thing, their graphical nature makes the dependence configuration explicit, as evidenced in Fig. 3 in the next
section. It captures BN takes into account, for example, dependencies between different environmental variables, which are not easily modelled with regression methods. Also, it allows to they can capture the often non-linear nature of those dependencies. The class of BNs used in this research includes several elements, whose specifics need to be explained before the actual hydrological model is presented.

First of all, consider a set of random variables \((X_1, X_2, \ldots, X_n)\), which could be discrete, continuous, or both. This distinction defines the different types of BNs. Here, more suitable is In this paper, we build a continuous BN, since our environmental data are continuous. Furthermore of this sort. Also, discrete BNs are only efficient for small models with variables having a limited number of states. That is because of the way the (conditional) probabilities are calculated, as we explain later on. The random variables are represented as “nodes” of the BN, while the dependencies between them are represented as “arcs” joining different nodes. An arc represents the (conditional) correlation between two variables, and has a defined direction. The node whose arc points into the direction of another node is known as the “parent”, while the node on the other “receiving” end of the arc is its “child”. A set of nodes and arcs forms the eponymous “network” of the BN. The arcs have to connect the nodes in such a manner that the graph is acyclic, i.e. if we chose any node and follow strictly the direction of all arcs in a path, we will not end up at the same node. Each variable is conditionally independent of all its predecessors given its parents. Therefore, each variable has a conditional probability function given its parents, and the joint probability can be expressed as:

\[
\mathbb{f}_{X_1X_2\ldots X_n}(x_1, x_2, \ldots, x_n) = \prod_{i=1}^{n} \mathbb{f}_{X_i|Pa(X_i)}(x_i|x_{Pa(X_i)})
\]

where \(Pa(X_i)\) is the set of parent nodes of \(X_i\), with \(i = 1, \ldots, n\). Naturally, if there are no parents, \(\mathbb{f}_{X_i|Pa(X_i)} = \mathbb{f}_{X_i}\). We already see that one of the purposes of BNs, perhaps the main one, is updating the probability distributions of subsets of nodes, when evidence (observations) of a different subset becomes available. Hence, it is important not only to properly set-up the network with nodes and arcs, but also to choosing a good method to describe the dependencies. In case of a discrete network, this is done using conditional probability tables. In our model, node ‘Max discharge’ has 7 parents. In this case, therefore if each continuous node were to be discretized into 5 states, a probability table with \(5^7 = 78,125\) may be estimated by difference, as probabilities must add to 1. Thus, 312,500 probabilities would need to be specified. Similarly, if we were to discretize each node into 10 states, each node 90,000,000 probabilities would need to be specified. Even a discretization into 5 states for each node in our model would make the quantification prohibitive given the data available. Considering other nodes (node ‘Buildup’ has 4 continuous parents) would make it even more restrictive for the use of discrete BNs. Thus, in this paper we apply a continuous non-parametric BN to avoid the use of probability tables.

Meanwhile, By using a non-parametric continuous BN, we only need to specify an empirical marginal distribution for each variable and a rank correlation for each arc (Hanea et al. 2015). We use the usual estimator of the cumulative probability distribution:
\[ \hat{F}(x) = \frac{1}{n} \sum_{i=1}^{n} 1_{[x_i \leq x]} \] (3)

where \((x_1, \ldots, x_n)\) are the samples of a random variable, while \(1_{[x_i \leq x]} = 1\) over the set \(\{x_i \leq x\}\) and zero elsewhere.

Spearman’s rank correlations are used to parameterize one-parameter (conditional) copulas. A copula is, loosely, a joint distribution on the unit hypercube with uniform (0,1) margins. There are many types of copulas, described in detail by Joe (2014). Here, we use bivariate Gaussian copulas, an assumption that was tested against alternate distributions (Clayton and Gumbel copulas). Details of this calculation, and the validation of the whole Bayesian Network can be found in Supplement 1. The bivariate Gaussian copula \(C\) has the following cumulative distribution function:

\[ C_p(u, v) = \Phi_p(\Phi^{-1}(u), \Phi^{-1}(v)), (u, v) \in [0,1]^2 \] (4)

where \(\Phi\) is the standard normal distribution, \(\Phi^{-1}\) its inverse and \(\Phi_p\) the bivariate Gaussian cumulative distribution with (conditional) product moment correlation \(\rho\) between the two marginal uniform variates \(u\) and \(v\) in the interval [0,1]. In contrast to the copula specification, the non-parametric BN we apply in this study is parametrized by (conditional) rank correlations. This is because they are algebraically independent; hence, any number in the interval [-1,1] assigned to the arcs of the BN will warrant a positive definite correlation matrix. The rank correlation (denoted by \(r\)) of two random variables \(X_i\) and \(X_j\) with cumulative distribution functions \(F_{X_i}\) and \(F_{X_j}\) is the usual Pearson’s product moment correlation \(\rho\) computed with the ranks of \(X_i\) and \(X_j\), i.e.

\[ r(X_i, X_j) = \rho \left( F_{X_i}(X_i), F_{X_j}(X_j) \right) \] (5)

Conditional rank correlations are calculated as shown in eq. 5, except that the conditional distributions are used inside the arguments to the right of the equal sign. For the Gaussian copula conditional correlations are equal to partial correlations and these are constant. For a one-parameter bivariate copulas, eq. 5 becomes:

\[ r(X_i, X_j) = 12 \int_0^1 \int_0^1 C_\theta(u, v) \, du \, dv - 3 \] (6)

The conditional rank correlation of \(X_i\) and \(X_j\) given the random vector \(Z = z\) is the rank correlation calculated in the conditional distribution of \((X_i, X_j | Z = z)\). For each variable \(X_i\) with \(m\) parents \(Pa_1(X_i), \ldots, Pa_m(X_i)\) the arc \(Pa_j(X_i) \rightarrow X_i\) is associated with the rank correlation:

\[ \begin{align*}
  r(X_i, Pa_j(X_i)), & \quad j = 1 \\
  r(X_i, Pa_j(X_i) | Pa_1(X_i), \ldots, Pa_{j-1}(X_i)), & \quad j = 2, \ldots, m
\end{align*} \] (7)

where the index \(j\) is in the non-unique sampling order. For more details on the non-parametric Bayesian Networks we refer the reader to Hanea et al. (2015). After Having all the variables and parameters of the Bayesian Network are in place the joint distribution is uniquely determined. Under the Gaussian copula assumption, exact inference is available as well as efficient sampling procedures (for details, see Hanea et al. 2006). Here, 1000 samples were used each time we wanted to conditionalize the BN in order to derive an estimate of river discharges for a given location in our dataset. This number of samples is adequate
to approximate the conditional distributions of interest while keeping the procedure computationally feasible. The Bayesian Network for river discharges presented here was implemented in Matlab, however the software UniNet software programme for non-parametric BNs was also used to visualize and analyse the model during the study (for details, see Morales Nápoles et al. 2013).

2.5 Extreme discharge model

The final BN for extreme river discharges was derived through by testing many configurations involving around 30 variables. The It is important to note that a BN cannot neither be created uniquely in an automated manner, nor is it desirable to do so. Therefore, the BN in this study was built stepwise and assessed using a set of statistical measures presented in section 2.7. The final model is based on uses 8 variables and is presented in Fig. 3, with a histogram representing each variables’ distributions. The position of the nodes shows their hierarchy relative to the annual maximum of daily river discharge (MaxDischarge); the order in which different variables conditionalize on the river discharge distribution (using eq. 7) is clockwise. The (conditional) rank correlation coefficients are indicated at on the arcs. The variables and BN structure are described in more detail below.

Annual maximum of daily river discharge (MaxDischarge) in m³/s. The parents of this variable are all the remaining variables in the BN. By far the most important is the catchment area (Area) in km² which determines the scale of the processes in a river basin and is largely dependent on catchment steepness (Steepness) in m/km. This is because mountainous catchments are very small, divided by ranges, and only grow in size when many rivers join along the way to its drainage basin, crossing more planar regions. Steepness was calculated here using eq. 1; it is a proxy for terrain characteristics that influences the speed with which the water from rainfall moves down the slopes (Savenije 2010).

The climate model from EURO-CORDEX framework delivered two variables to the BN. First is the annual maximum of daily precipitation and snowmelt (MaxEvent) in mm. Both factors are relevant, though melting of snow cover is important only in some regions. Both events also often occur concurrently (as evidenced in the list of large European floods by Barredo 2007), so-hence using a summation of the two improved the performance of the BN. The variable has one parent, catchment steepness, as hilly and mountainous areas receive more precipitation, also in the form of snow. The second variable is the extreme runoff coefficient (RunoffCoef), a dimensionless indicator. It was constructed to include meteorological factors influencing the circulation of water in a catchment. Every climate model needs to represent this variable to take, taking into account factors such as soil moisture, evaporation and retention. The annual maximum of the climate model variable “total runoff” was obtained for each sample, and then divided by MaxEvent. This variable is dependent on catchment steepness, since in hilly/mountainous terrain conditions limit evaporation or retention. It should be noted that the values of these climate variables were calculated as an average of annual maxima derived for each grid cell separately, and not by identifying the largest single event that occurred in a given the catchment.

The BN is completed by three land cover types, all expressed as % of total catchment area. The statistics were obtained by choosing relevant classes from land cover datasets. First The first variable are represents lakes, which were and was
obtained using “water bodies” class in Corine Land Cover (CLC), with missing coverage supplemented by the water body layer in CCM2 database. Lakes retain water from rainfall or snowmelt, thus reducing river discharge. This node has two parents, catchment steepness and extreme runoff coefficient. Lakes, especially large ones, are more prevalent in post-glacial plains of northern Europe, though increase lake cover is observed also in the mountains. In both those areas the runoff coefficients are higher, due to lower temperatures and more prevalence of impermeable soils, with the same factors influencing both (like soils or temperature). Second The second variable is represents marshes, which are defined by CLC as three classes “inland marshes”, “peat bogs” and “salt marshes”, while from Global Land Cover 2000 (GLC) “regularly flooded shrub and/or herbaceous cover” class was used here. Similarly to lakes, marshes increase retention in a catchment. They often occur in the same areas as lakes, with soils and climatology also having influence (as estimated by the runoff coefficient). Lastly, the build-up areas (Buildup) variables contain the “artificial surfaces” class from CLC or GLC. Construction increases the amount of impervious cover in a catchment, seals the soil, reducing infiltration, while water management systems collect the rainfall and routes it directly to rivers. This variable is influenced, in order, by catchment steepness (flat areas are preferred for construction), runoff coefficient (which is higher in colder areas), lakes and marshes (less space available for construction).

In order to estimate river discharge in an ungauged catchment, the BN is updated, i.e. the value of the node or set of nodes (other than discharge) is defined based on the new evidence, which are the observations corresponding to that particular catchment, i.e. new evidence. Fig. 4 shows the effects of updating on the example of Basel station in Switzerland (meteorological data pertain to the year 2005). Conditionalizing on only two variables: catchment area and steepness changed the mean of the distribution from 341 to 1740 m³/s. Knowing all seven variables that are parents of the river discharge node, we obtain an estimate of river discharge of 2819 m³/s. In this case, the estimate is fairly accurate, as discharge of 3212 m³/s was actually measured. The same procedure was applied to all rivers in the domain. Additional examples of conditionalization of the BN can be found in Supplement 1. It should be noted that the discharge in each river section was estimated independently from another section in the same river using data for the entire upstream area.

In addition to validation of the method, we apply it to model the influence of future climate predictions using from EC-EARTH-COSMO_4.8_clm17 (Figure 8) and EC-HadGEM2-ES-RACMO22E (Figure S9) climate model runs. As noted before, land cover statistics are fixed in time, therefore only the climate variables change over time in the prediction. Future changes were calculated for two climate scenarios RCP 4.5 and RCP 8.5. Those “representative concentration pathways” indicate changes in future physical and socio-economic environment that would cause, by 2100, increase in radiative forcing by 4.5 or 8.5 W/m² (Moss et al. 2010).

2.6 Return periods of discharges

Annual maxima of daily river discharges calculated using by the BN were used to perform a frequency analysis. Only stations with long data series were used, i.e. those with at least 30 years of discharge observations. To find an optimal model for estimating the marginal probability distribution of annual maxima of discharges, we used the Akaike Information Criterion
(AIC) measure (Mutua 1994). It showed significantly between variability among stations. On average, the AIC value was the lowest for the Generalized Extreme Value (GEV) distribution, indicating that it was the best fit over 15 other tested distributions, such as generalized Pareto, Gamma, Lognormal or Weibull. This three-parameter distribution, however, gave very large errors for some stations. Therefore, to avoid completely unrealistic estimates in the database, we decided to use the two-parameter Gumbel distribution, which is essentially the GEV distribution with the shape parameter equal zero. This distribution was previously used in several large-scale flood hazard studies (Dankers and Feyen 2008, Hirabayashi et al. 2013, Winsemius et al. 2013, Alfieri et al. 2014). In order to calculate discharge \( Q \) with probability of occurrence \( p \), the following equation is used:

\[
Q_p = \mu - \sigma \ln(-\ln(1 - p))
\]

where \( \mu \) is the location parameter and \( \sigma \) is the scale parameter. Parameters were fitted using maximum likelihood estimation (Katz et al. 2002, Gelman et al. 2013). The extreme value analysis assumes the stationarity of the river discharge series. Using Spearman’s rank correlation we found that in 918 of 1125 gauges used to obtain return periods the trend was not significant at level of significance of 0.05.

In order to maximise the number of stations available for validation, 30-year time periods were used in the calculation. 30 years were used because such a time period maximises the number of stations available for validation. Also, this time span is commonly used in climate research. The main validation set consists of 958 stations with 1971–2000 data, 129 with 1961–90 data and 38 with 1951–80 data. That is, in total out of 1841 used to quantify the BN. For further analysis, we made the calculation for all stations with data for a given time period; 1981–2010 period was added as well, utilizing modelled discharge estimates based on RCP 4.5 climate scenario for the years 2006–2010. Additionally, subsets comprising different regions of Europe and catchment size were also analysed.

### 2.7 Measures for validation of the model’s results

Accurate estimation of return periods of extreme discharges, as well as mean annual maximum, are the desired outcomes of the Bayesian Network model. Quality of return periods and average maxima simulations were evaluated using a set of three measures: coefficient of determination, Nash-Sutcliffe efficiency and RMSE-observations standard deviation ratio. Those methods were selected because they have also been used in other studies (e.g. Rojas et al. 2011) and they were included in an overview of most important measures by Moriasi et al. (2007). Firstly, the Pearson’s coefficient of determination (\( R^2 \)) was used to measure the correlation between observed and simulated values. In Kurowicka and Cooke (2006) it is noted that \( R^2 \) actually factorizes into a function of the conditional rank correlations attached to the BN. Secondly, Nash-Sutcliffe efficiency (\( I_{NSE} \)) was applied to measure bias of the model. Its maximum value is 1, which means a plot of observed vs simulated
data fits the 1:1 line (no bias), while a value below 0 (down to \(-\infty\)) indicates that the mean of the observations is a better predictor than the simulated value. The relevant equation is as follows:

\[
I_{NSE} = 1 - \left\{ \frac{\sum_{i=1}^{n}(x_i^{obs} - x_i^{sim})^2}{\sum_{i=1}^{n}(x_i^{obs} - x^{mean})^2} \right\}
\]

(9)

where \(x_i^{obs}\) is the \(i\)-th observation of a variable, \(x_i^{sim}\) is the \(i\)-th simulated value of that variable and \(x^{mean}\) is the mean of observations. The final measure is root mean square error (\(I_{RMSE}\))-observations standard deviation ratio (\(I_{RSR}\)). It standardizes the RMSE based on the standard deviation of observations (\(I_{SDobs}\)):

\[
I_{RSR} = \frac{I_{RMSE}}{I_{SDobs}} = \frac{\sqrt{\sum_{i=1}^{n}(x_i^{obs} - x_i^{sim})^2}}{\sqrt{\sum_{i=1}^{n}(x_i^{obs} - x^{mean})^2}}
\]

(10)

To further investigate the relative accuracy of the method in light of alternate models, we performed a RFA analysis, as presented by Smith et al. (2015). This required us to obtain some supplementary data. Each river gauge station had to be assigned to one of five climate zones according to the Köppen-Geiger classification; a world map by Kottek et al. (2006) was used for that purpose. Overall, 65% of stations with long records in our sample are located in the temperate climate zone, 30% in continental, 4% in polar and 1% in arid. Additionally, mean annual rainfall was derived from CORDEX climate data. The final input information was catchment area, readily available from our datasets. In order to estimate discharge in the RFA, a given station had to be assigned to one of the 82 clusters included in the RFA. The first criterion is the climate zone, which allocated a station to a group of clusters. Then, the Euclidean distance to the each cluster centroid (defined through a logarithm of area and rainfall) was calculated. Afterwards, “mean annual flood” equation (see Smith et al. 2015) was solved using the coefficients from the nearest cluster as well as catchment area and annual rainfall, providing us with \(Q_{MAMX}\). Finally, cluster-specific GEV distribution parameters were then applied to obtain return periods of extreme discharges.

3 Results

In this section, extreme river discharges calculated using the Bayesian Network are compared with observed river discharges. Additionally, we present the results of applying the method to estimate the influence of climate change on discharges in Europe. Here, we present the results using EC-EARTH-COSMO_4.8_clm17 climate models. Results obtained with alternate climate models can be found in Supplement 2.

3.1 Validation of the model’s results

Extreme river discharges estimates obtained from the Bayesian Network are presented and compared with observed discharges in Fig. 5 and 6. The graphs include the mean annual maximum of daily discharge (\(Q_{MAMX}\)) and three return
periods of discharges. In Fig. 6 we show a comparison of specific river discharges, i.e. runoff divided by the respective catchment areas (Wrede et al. 2013). The former shows the highest performance with both $R^2$ and $I_{NSE}$ at 0.92, while accuracy of simulated discharge fitted to Gumbel distribution decreases with the probability of occurrence. The 10-year discharge ($Q_{10}$) has almost the same performance as $Q_{MAMX}$, while the 1000-year ($Q_{1000}$) discharge noticeably deviates from the 1:1 line, mainly for very large rivers. It should be also remembered that the return periods were based only on 30-year series, therefore a 100- or 1000-year discharge includes the uncertainty of extrapolation of the return periods. However, the $I_{NSE}$ value is still good, and $R^2$ changes moderately. The $R^2$ drops when considering specific river discharge, to 0.52 for $Q_{MAMX}$ when considering specific river discharge and 0.44 for 100-year discharge, with $I_{NSE}$ at 0.43 in both cases. Again, performance is slightly higher for 10-year discharge and drops approaching 1000-year discharge. It is also interesting to notice that the rank correlations for all four cases discussed previously ($Q_{MAMX}$, $Q_{1000}$, $Q_{100}$, $Q_{10}$) are in the order of 0.8 and their bivariate distribution does not present large asymmetries (Fig. S5 in Supplement 2). This could be indication that a method based on copulas could also be used as for bias correction, however further investigation of this observation is investigating this fact further falls outside of the scope of this paper.

Performance of the model by time period, region or catchment area was also analysed also in more detail, by time period, region or catchment area (Table 2). For four different time periods, where availability of stations varies, the results of the validation are almost identical. Only for 1981–2010 it is slightly lower, because it is partially outside the timespan of the historical scenario of EURO-CORDEX; for 2006–2010, data from RCP 4.5 climate change scenario run had to be used to fill the missing information for 2006–2010. Much more variations in the quality of the simulations is observed when dividing the results by geographical regions (their definitions correspond to the regionalisation of the CCM2 catchment database). Western Europe (comprised mainly of France, Belgium, the Netherlands and Rhine river basin) had particularly good results for $Q_{MAMX}$, followed by Danube river basin and Scandinavia (roughly defined as Sweden and Norway). The lowest correlation for $Q_{MAMX}$ was observed in the Iberian Peninsula (Spain and Portugal), while Central Europe (mainly Poland, Lithuania, Denmark and north-east Germany) had the highest $I_{NSE}$ values. Iberia had the lowest performance for $Q_{100}$, while Western Europe recorded the highest correlation, and Scandinavia the best score in $I_{NSE}$ and $I_{RSR}$. Central European and Scandinavian stations’ error was lower and $I_{NSE}$ values higher for 100-year return period compared to $Q_{MAMX}$. No region dropped below acceptable levels (i.e. $R^2$ or $I_{NSE}$ a value of 0.5, according to Moriasi et al. 2007), albeit stations in the Iberia and “other regions” have noticeably lower performance. In the case of Spain, to which almost all stations collected for the Iberian Peninsula belong, discharges tend to be overestimated, which may point to the influence of reservoirs on river flow. Indeed, many Spanish stations with large errors were found to be just downstream of large dams. Meanwhile, Finally, “other regions” is a grouping of a small number of stations scattered around Europe, mainly from Finland, Italy and Iceland. Those areas, containing many rivers in both arid and polar climates, are underrepresented in the quantification of the Bayesian Network, hence which may provide a potential justification reason for their lower performance.
In Fig. 5 it can be seen that the amount of scatter in the plot increases for rivers with smaller discharges. Detailed results in Table 2 show that the performance of the model drops for smallest catchments, especially for those below 100 km² (177 catchments). For others, above 500 km², the $R^2$ and $I_{NSE}$ values are mostly in the range of 0.5–0.6 for specific discharges, as when considering all stations. Additionally, to validate the robustness of the method, we did a split-sample test. Stations were randomly divided into two sets. Data from 917 stations were used to quantify the Bayesian Network in order to simulate discharges in the remaining 924 stations. Of the latter, 586 stations had at least three full decades of discharge observations, which allowed us to make a comparison with simulated discharge. The validation result was almost identical with reported for the full quantification, and even a-notch better results ($R^2=0.94$ and $I_{NSE}=0.93$) were observed for $Q_{MAMX}$, while for $Q_{100}$ the same value of $I_{NSE}$ was calculated and $R^2$ equalled 0.90. Still, performance for individual stations varies. A selection of observed and simulated discharges, both annual maxima and fitted to Gumbel distribution, is presented in Fig. 7. In some stations, there is a very close fit, while in others either the discharge is overestimated, or the distributions have different shapes. This is however not atypical even for more local studies.

The final analysis in this section is the comparison of the BN model and Regional Frequency Analysis (RFA). Using RFA, estimates of extreme discharge were obtained for all 1125 stations with long records, which were compared with to discharges in Fig. 9. In the case of $Q_{100}$, Gumbel-distributed discharges were used, as the performance with GEV distribution was slightly lower. The performance of both BN and RFA models is visually similar, though the BN recorded higher correlation and less bias than the RFA. Less scatter can be observed in upper and lower ranges of discharges, with similar performance in the middle. Using specific river discharges (Fig. 10) the performance of both methods was lower, but still much better for the BN: $I_{NSE}$, for example, was negative for both $Q_{MAMX}$ and $Q_{100}$ when using RFA, in contrast to a value of 0.43 for the BN. RFA was devised as a global method instead of a regional one, but at the same time it is in fact a set of 82 regional approximations of hydrological processes. Here, we analyse contributing factors of extreme discharges all together, achieving comparable or even better results.

### 3.2 River discharges in Europe

Calculation of river discharges utilizing data from EURO-CORDEX climate simulations was done for years 1950–2100, and are presented here in three time slices: 1971–2000, 2021–2050 and 2071–2100. The first period is from the historical “control” run, while the other two were analysed for two emission scenarios: RCP 4.5 and RCP 8.5. Projected trends calculated from the data are presented in Fig. 8. For the sake of clarity, only rivers with catchment area above 500 km² are presented in the picture; full-scale maps of discharges were included in the Supplement. Aggregate statistics by region and catchment size were included in Table 3. In the description we focus on 100-year discharge, but the trends are mostly also representative for other return periods.
The projected trends in Europe are very diversified. For Europe as a whole, there is a slight 4–7% increase in discharges with a 100-year return period ($Q_{100}$), with the biggest change observed in the 2021–2050 RCP 8.5 scenario. Along 34–44% of river length in Europe, $Q_{100}$ is projected to increase at least by 10%, depending on scenario. Yet, along 16–21% of river length a decrease by more than 10% is expected; with only small changes (±10%) for the remaining 35–49%. In RCP 8.5 both increases and decreases of $Q_{100}$ are more prominent than in RCP 4.5. In effect, $Q_{100}$ in the 2071–2100 RCP 8.5 scenario is projected to correspond to 176-year discharge under present climate (1971–2000), if we take the median value. This value is slightly lower in mid-century, and in end-century for RCP 4.5, with the smallest change compared to present climate in the 2021–2050 RCP 4.5 scenario.

Between regions, by mid-century, the largest average increases in extreme discharges are expected in the Iberian Peninsula and Danube basin (RCP 4.5), while $Q_{100}$ in Central Europe (i.e. mainly Elbe, Oder and Vistula river basins) is projected to surge even more in RCP 8.5. By the end of the century, however, Southern Europe (comprised mostly of Italy) will experience the is the region were the biggest average increase was observed in the simulations. On the other hand, $Q_{100}$ is projected to decrease on average in the British Isles in all four scenarios, in North-East Europe (Finland, north-west Russia, the Baltics) in three scenarios, in Scandinavia in two and in South-East Europe (mainly Greece) in one. Those discrepancies are the result of several trends, namely changes in extreme precipitation, snowmelt and runoff coefficient. The first is projected to increase across the continent, while the other two decrease at the same time, with some exceptions. Decline in snowmelt, a consequence of thinner snow cover, will contribute to lower extreme discharges in parts of Scandinavia and Scotland. However, in most of Sweden, Finland and other areas, less snowmelt will be offset by more rainfall. Lower precipitation is expected only in small, scattered patches of Europe, most noticeably in southern Spain. At the same time, an increase of the runoff coefficient could be observed in predictions for the Iberian Peninsula and western Europe, with decreases in the remainder of the continent. Higher temperatures and less soil moisture are contributing factors to those trends.

In Table 3 projected trends in $Q_{100}$ were also provided per catchment size. The differences in average increase of discharges are very small, and partially caused by their uneven distribution in Europe. Median return periods show more diversity, since relative increase in discharge by certain increment of return period typically gets smaller as the river grows in size. Most importantly, this breakdown shows that the method is able to detect trends in discharge in both large and small rivers.

4 Discussion

The results presented in the previous section, however encouraging on their own, have to be contrasted with compared to other existing studies. Such analysis is presented in section 4.1. Section 4.2 presents, while in the subsequent subsection a discussion is carried out about of the limitations of the method and the uncertainties in the model’s set-up and results. Finally, in section 4.3, ongoing and planned developments of the BN are presented.
4.1 Comparison with other models

The accuracy of the Bayesian Network model of extreme river discharges can be compared, directly or indirectly, with results of other statistical and physical models. In case of the former, a comparison with RFA method was shown in section 3.1. For the latter, reported values of $R^2$ and $I_{NSE}$ from several studies could be obtained.

Studies with measures of model performance comparable with this one were summarised in Table 4. All of them were based on the LISFLOOD model, forced by a large variety of climate models. Still, the validation of those hydrological models was mainly based on Global Runoff Data Centre discharge data, similarly to this study. Consequently, though a smaller number of gauge stations was used, they mostly overlap with the ones utilized in this study. Nevertheless, the correlation between observed and simulated mean annual maxima of daily discharges ($Q_{MAMX}$), measured by $R^2$, was between 0.86 and 0.94. The corresponding value in this study is within this range. Only one other study (Dankers and Feyen 2008) reported $R^2$ for discharge with different return periods ($Q_{20}, Q_{50}, Q_{100}$). When compared with the results using the BN model, and our results are slightly higher. It should be noted that in that the aforementioned analysis, using Gumbel distribution (like in this study) yielded better correlation than Generalized Extreme Value (GEV) distribution. Only two studies reported $I_{NSE}$ values. Most interestingly, Rojas et al. (2011) show that the performance of the hydrological model changed significantly depending on how climate data were treated. The authors noted large biases in modelled precipitation data, and made a correction based on observational datasets. This modification of climate data output slightly improved the correlation, but most importantly the $I_{NSE}$ went from a negative value, indicating poor performance, to a value close to perfect fit with a 1:1 line. In this study, no modifications to climate data were made and yet $I_{NSE}$ values for our statistical model are in the range of a physical model forced by bias-corrected climate data. Of course the reported validation results are not perfectly comparable with this analysis due, since the described studies focused on relatively large rivers (those more than ca. 1000 km$^2$ catchment area) and used ENSEMBLES regional climate simulations, which are several years older than the CORDEX simulations employed here. Additionally, $R^2$ and $I_{NSE}$ are not the only measures available. Dankers and Feyen (2008) report that the error in simulating $Q_{MAMX}$ was bigger than 50% in 24–25% of stations and more than 100% in 6–8%. In this study, for comparable river size, i.e. with extreme discharge of ca. 100 m$^3$/s and more, those values are 34% and 11%. Still, in overall the performance of the Bayesian Network can be described as similar to LISFLOOD model in estimating annual extremes.

4.2 Limitations and uncertainties

The Bayesian Network model, despite its overall high performance, has lower accuracy over some certain regions, where outliers are observed. Some of the uncertainties and limitations of the model are immanent properties of large-scale hydrological simulations, while others are specific to how the method was conceived, and what assumptions and data were included. One of the foremost aspects belonging to the first group category is that the method assumes natural flow in the catchment. Hydraulic structures, such as large dams, can have profound influence on extreme discharges, as many were developed as a flood-reducing measure. As mentioned in the results section, flows in Spanish rivers were generally
overestimated and reservoirs may provide a likely explanation. Continental or global scale models routinely omit this aspect, as there is not enough information available to incorporate the existence of reservoirs or their operation. They have different functions (flood protection, flow regulation, water supply) and function according to various operational procedures. The BN model includes reservoirs only indirectly; they count as lakes, and therefore contribute to the percentage of the catchment covered by water bodies, thus having and have a negative influence of extreme discharge. However, dams can have a much larger impact on discharges, as indicated by the lower performance of the methods in Spain, where large dams are plenty. In total, 326 large dams are within the catchments of the stations used in this study, according to the GRanD database (Lehner et al. 2008). Additionally, the conditions in the catchment may change over the timespan of the analysis of discharge data (1950–2005), due to reservoir construction or river regulation, or simply because of land use developments. Currently a single snapshot of European land cover is used (from around the year 2000), but the area covered by lakes, marshes and particularly artificial surfaces is dynamic. In our analysis there was very little difference in performance between different time periods, but this aspect could be relevant locally.

The configuration of the Bayesian Network presented here was the best one we found, but may not be the only solution possible, or the best one there could be. In Paprotny and Morales Nápoles (2015) the set-up of the model was slightly different, with unconsolidated deposits (calculated as a fraction of all soil types in a catchment) used instead of the runoff coefficient. It can be noticed that despite several soil datasets being mentioned in the methodology (section 2.3), none made it the final configuration of the model. Low resolution and limited thematic accuracy of global soil data is likely the cause. Several other variables describing terrain, climate or land cover mentioned in section 2.3 were not included, as adding them did not improve the model. However, one alternative configuration worth mentioning is a BN incorporating terrain classification based on height-above-nearest drainage (HAND). Replacing lake and marsh cover with “wetlands” and “hillslopes” identified in the digital elevation model (see Gharani et al. 2014) caused only fractional drop in performance. Given that land cover data for Europe has very high resolution and good accuracy, this approach may give better results in areas with less satisfactory data such as the developing countries.

Some issues are related with the datasets used. Discharge data are daily values, rather than absolute peak flows, as that variable was the only one available from the main source of information, i.e. the Global Runoff Data Centre. Yet, Polish data were only available as sub-daily maxima, which did not affect much the accuracy for Poland or Europe, but is nonetheless a slight inconsistency. More crucially, daily discharge is not adequate to model flash floods, or floods of short duration, or floods in small catchments. These events can occur in matter of minutes, and do not even require a outside of river beds. Also, the model utilizes daily precipitation and snowmelt, which also may not be accurate for large catchments, where the biggest floods are caused by rainfalls lasting many days. Potential incorporation of different timespans of flood-inducing meteorological events is yet to be analysed. In some regions the amount of river gauge station data was very limited, mainly in south-eastern Europe, while in others (northern and western Europe) was abundant, making the sample less representative.
The river gauge observations might still contain errors, even though they were quality-checked by the providers; they could also be systema
tically inaccurate due to e.g. outdated rating curves.

Further concerns are related with the river and catchment dataset CCM2. It has lower accuracy in areas with low relief energy, otherwise known as plains. Slightest inaccuracies in the DEM result in improper delimitation of catchments in such regions. Large numbers of lakes in post-glacial parts of Europe can also result in sometimes substantial errors. For instance, $I_{NSE}$ value for $Q_{MAMX}$ for mountainous Norway is 0.90, while for Sweden, with its lake-filled landscape, it drops to 0.71. River gauge stations, for which there was a significant difference between catchment area in CCM2 and the corresponding value in the stations’ metadata, were removed from the sample. The improperly divided basins still exist in our final database of simulated extreme discharges, though. This also involves omission of most artificial channels and all cases of bifurcation, river deltas included.

Climate data from CORDEX have the highest resolution available, yet biases in representing rainfall, snowmelt and runoff could influence the results. As addressed can be noticed in section 4.1, bias-correction of precipitation significantly improved performance of LISFLOOD hydrological model, therefore leaving room for further enhancements of the method. Another issue is related with climate change scenarios used to construct the database of discharges. The difference between RCP 4.5 and RCP 8.5 scenarios is sometimes very large; as witnessed in Fig. 7. This alone illustrates major uncertainty related with future projections of climate. For the historical period, the use of an alternative CORDEX model and a climate reanalysis has shown (Supplement 2) that the BN model’s performance depends on the climate model used, yet it is still considerably better than the regional frequency analysis.

Finally, the underlying dependence structure requires further investigation, since some of the bivariate distributions of variables indicate that a non-Gaussian copula could be a better model (see Supplement 1 for details). Other copulas could potentially be used since, as for some distributions tail dependence and other asymmetries may be present, even though the normal copula works well most of the time. Skewness, for example, may be modelled by copulas based on mixture distributions. This would correspond to copulas with more than two parameters (Joe 2014).

4.3 Applications and further developments

The method was originally conceived to provide extreme discharge estimates that could be used for pan-European hazard mapping. As shown in the previous sections, it has the BN provides similar accuracy results when compared to existing hydrological models, yet it is much faster. For hydrodynamic modelling of water levels (Paprotny et al. 2017), catchments with area greater than 100 km$^2$ where selected, both to further reduce calculation time and due to limited applicability of the BN model to very small catchments. The calculation of annual maximum discharge for 151 years, including 95 years in two climate change scenarios, in a domain of almost 156,000 river sections above the threshold, and obtaining return periods of flood events, takes less than a day on a desktop PC. The exact value depends on the number of samples used when conditionalizing the BN, and the number of samples used to quantify the BN. Nevertheless, the method can reduce time needed
to perform a flood hazard analysis, both continental-scale and local, as long as annual extremes are relevant for a particular study.

The results of this study – extreme discharges with certain return periods under present and future climate for all river sections in the domain – are publicly available online (Paprotny and Morales Nápoles 2016). The dataset was formatted in GIS in such a manner, that it can be easily combined with the CCM2 river and catchment database. The files include a total of 10 different return periods of discharges (2–1000 years) and 5 scenarios, the same as described in section 3.2. Additionally, for each future scenario, change in the return periods of discharge with certain probability of occurrence in compared to 1971–2000 was calculated and included in dataset. Flood hazard maps that utilized those results are also accessible and summarized in Fig. 8 and Fig. S10; however, further discussion about them is outside the scope of this paper. This is definitely a line for future research recommended by the authors, with first application presented in Paprotny et al. (2017). We should note, however, that all the databases were published with the intention of analysing them on a European scale, and users should be careful applying them at local scale, especially for small and medium catchments (with an area of less than 500 km²).

The method’s scope was limited so far to Europe, but investigation is also ongoing on applying the method to other regions, globally. Currently, data from United States and Mexico are being analysed. There is a very large number of river gauge observations available for the contiguous US, while its southern neighbour the number and quality of historical records with good quality is limited. These case studies provide interesting challenges when compared to Europe. Mexico also lays mostly within tropical and arid climate zones, which is in stark contrast to Europe. The United States are also very geographically diversified and its biggest river system – the Mississippi-Missouri basin – is almost four times larger than the Danube basin. Moreover, for these countries global spatial datasets will be used, which have a lower resolution than those utilized in this study. It is possible, for instance, to quantify the BN model with those datasets and analyse its performance relative to the European quantification presented in this paper, as well as to combine those data. In this way, the model’s configuration with seven variables can be challenged, as the one risk is that the method is overfitting the data from Europe. But again, this could only be definitely resolved by testing the model in other geographical areas of the world. As a first check, Couasnon (2017) applied the model for the contiguous United States, indicating that the European quantification performed generally well, though much less accuracy was observed for arid and hurricane-influenced parts of the country than in those with temperate climate. Quantification based on US or combined (US/Europe) data performed less well, though for any variant the results were better than when using RFA, which was originally validated for that area by Smith et al. (2015). Finally, the model could be potentially evaluated not only using all variables, but conditionalized only on some of them, as observations for all variables might not be available in a given location.
5 Conclusions

In this paper we presented a first attempt to model extreme river discharges in Europe using Bayesian Networks. The method revisits the old concept of estimating discharges using only geographical properties of catchments, but employing an entirely new approach. Instead of a usual regression analysis, we determine the (conditional) correlations between different variables describing the catchments with copulas and a non-parametric BN. We show that the model has comparable accuracy to other large-scale hydrological models in simulating mean annual maxima and return periods of daily discharges, and higher performance than a regional frequency analysis. The data necessary to apply the method can be obtained from pan-European (or global) databases for any location in the continent (or other locations where global data is available). In this sense, the method can be used to create basic flood scenarios at any ungauged location where data for these variables are available. For that reason it was used to provide estimates of extreme river discharges for both present and future climate in all rivers in a domain covering most of the continent. However, the accuracy at different ungauged locations varies to some degree. The best performance was found in Scandinavia, western Europe and the Danube basin, while the lowest was observed in southern Europe, especially in the Iberian Peninsula, however, as seen in Table 2, could differ. Trends in discharges were found to be very diversified, while the database itself will be applied to delimiting flood hazard zones in a separate study. Especially for future climate scenarios, further research regarding discharge estimates with our model is recommended.

There are several advantages of our approach. It is that it has low computational expense. The method is also flexible as its configuration could be easily modified, and the model can be used even if not all variables for a given location are available. At the same time it allows to perform sensitivity analysis of different variables on extreme discharges, as well as easily incorporate changes in climate or land use over time. It purely relies on the statistical distributions and statistical dependence of catchment descriptors, without any empirical modifiers or clustering typical for other statistical methods. The model also has a graphical nature, which makes its formulation is explicit. The aim was to make the method universal, and, even though it was so far only comprehensively tested for Europe, its overall performance is encouraging. The accuracy of the model changes relatively little between regions and time periods, as well as when a split-sample test is applied. The disadvantages are mostly typical for other large-scale models, such as assumption of natural flow conditions in the rivers and lower performance in smaller catchments. Validation has shown that for catchments smaller than 500 km², and especially than 100 km², performance is significantly lower than for larger ones, due to increasing influence of local factors. The method was also crafted only for annual maxima of discharges, with the purpose of accurately estimating return periods rather than discharges in a particular year. But again, this is the most relevant parameter in flood hazard analysis. The method will be further developed and tested in other parts of the world.

30 Data availability

This work relied entirely on public data as inputs, which are available from the providers cited in the paper. Results of the work can be downloaded from an online repository (Paprotny and Morales Nápoles 2016).
Acknowledgements

This work was supported by European Union’s Seventh Framework Programme under “Risk analysis of infrastructure networks in response to extreme weather” (RAIN) project, grant no. 608166. The authors would like to thank the Global Runoff Data Centre in Koblenz, Germany, for kindly providing a large part of river gauge data used in this study. The work described herein benefited from useful comments by S. N. Jonkman, H. H. G. Savenije, A. Sebastian, A. Sikorska and two anonymous reviewers.
