Abstract: Under the Grain for Green project in China, vegetation recovery constructions have been widely implemented on the Loess Plateau for the purpose of soil and water conservation. Now it becomes controversial whether the recovery constructions of vegetation, particularly forest, is reducing streamflow in rivers of the Yellow River Basin. In this study, we choose the Wei River, the largest branch of the Yellow River and implemented with revegetation constructions, as the study area. To do that, we apply the widely used Soil and Water Assessment Tool (SWAT) model for the upper and middle reaches of the Wei River basin. The SWAT model was forced with daily observed meteorological forcings (1960-2009), calibrated against daily streamflow for 1960-1969, validated for the period of 1970-1979 and used for analysis for 1980-2009. To investigate the impact of the LUCC (Land Use and land Cover Change) on the streamflow, we firstly use two observed land use maps of 1980 and 2005 that are based on national land survey statistics emerged with satellite observations. We found that the mean streamflow generated by using the 2005 land use map decreased in comparison with that using the 1980 one, with the same meteorological forcings. Of particular interest here, we found the streamflow decreased in agricultural land but increased in forest area. More specifically, the surface runoff, soil flow and baseflow all decreased in agricultural land, while the soil flow and baseflow of forest were increased. To investigate that, we then designed five scenarios including (S1) the present land use (1980), (S2) 10%, (S3) 20%, (S4) 40% and (S5) 100% of agricultural land was converted into forest. We found that the streamflow consistently increased with agricultural land converted into forest by about 7.4 mm per 10%. Our modeling results suggest that forest recovery constructions have positive impact on both soil flow and baseflow compensating reduced surface runoff, which leads to a slight increase in streamflow in the Wei River with mixed landscapes of Loess Plateau and earth-rock mountain.
1. Introduction

Since 1999, China’s Grain for Green project has greatly increased the vegetation cover (Chen et al., 2015) and the total conversion area reaches 29.9 million ha until 2014 (Li, 2015). And the proposals are to further return another 2.83 million ha farmland to forest and grassland by 2020 (NDRC, 2014). The establishment of either forest or grassland on degraded cropland has been proposed as an effective approach to mitigating climate change because these types of land use can increase soil carbon stocks (Yan et al., 2012; Deng et al., 2013). Implementation of large scalar Grain for Green project is undoubtedly one type of geoengineering which not only mitigates climate change but also is expected to alter hydrological cycle.

Some researchers have urged a cessation on Grain for Green expansion on the Loess Plateau of China and argued that continued expansion of revegetation would cause more harm than good to communities and the environment (Chen et al., 2015). One important reason was that the Grain for Green project lead to annual streamflow of the Yellow River declining (Chen et al., 2015; Li, 2001). Land use change can disrupt the surface water balance and the partitioning of precipitation into evapotranspiration, runoff, and groundwater flow (Sriwongsitanon and Taesombat, 2011; Foley et al., 2005; Wagner et al., 2013). Large scale revegetation constructions change hydrologic cycle process and distribution of water resources. There are three controversial points of view about the impact of vegetation on streamflow as a whole. Quite a few catchment studies indicated that annual streamflow decreased with revegetation increased or vegetation destruction (Zhang and Hiscock, 2010; Bosch and Hewlett, 1982; VanShaar et al., 2002; Waring et al., 1998; Mango et al., 2011; Woodward et al., 2014; Farley et al., 2005; Liu and Zhong, 1978; Hibbert, 2001), where some catchment studies indicated baseflow of forests was lower due to high
evapotranspiration rates (Lørup et al., 1998; Lorup and Hansen, 1997; Smith and Scott, 1992),
while other studies indicated the baseflow increased in the dry season due to higher infiltration
and recharge of subsurface storage (the “sponge-effect hypothesis”) (Price, 2011; Lørup et al.,
1998; Ogden et al., 2013). In contrast, other studies showed that vegetation has a positive impact
on streamflow (Tobella et al., 2014; Li et al., 2001) or no impact on streamflow (Wang, 2000;
Beck et al., 2013).

To interpret the controversial results, it was argued that the impact of vegetation on annual
streamflow depends on watershed area and the relationship between them was negative in smaller
watershed and positive in larger watershed (Huang et al., 2009; Zhang, 1984). Some researchers
indicated tree planting has both negative and positive effects on water resources and the overall
effect was the result of a balance between them, which were strongly dependant on tree density
(Tobella et al., 2014). Some results showed that regions of increasing streamflow with forest
usually occur at high latitude area (Huang, 1982). The speculation was that snow may be blown
away or to wooded areas from woodless area, which could enhance the coefficient of streamflow
but these factors would be weaker over low to middle latitude than that in high latitude (Huang,
1982). Further, vegetation may change hydrological cycle as follows (Le Maitre et al., 1999):
redirection of precipitation by the canopy; branches, stem and litter tends to intercept more water
into the soil; roots may provide channels for the flow infiltrating to groundwater and extract soil
water as evaporation. Hence different results have led to contentious relationship between
vegetation and streamflow (Bradshaw et al., 2007; Dijk et al., 2009).

The Wei River is one main branch of the Yellow River and has been widely implemented soil
and water conservation since the 1980s (Fig. 1). Until 2006, the treated area accounted for about
one third of the watershed, more than 43% of which was the forestation in the main stream of Wei River basin. Meanwhile the annual runoff of the Wei River has decreased significantly since the 1980s (Liu and Hu, 2006; Lin and Li, 2010; Wang et al., 2011). Since the 1990s, the streamflow has sharply dropped and the observed annual streamflow of Linjiaucun station in the 1990s was less than one third of that before 1990s. Meanwhile the Wei River basin consists of Loess Plateau landscape and earth-rock mountain landscape, which induce different mechanisms transforming rainfall into streamflow. On the Loess Plateau, it was found that there is a drying layer of soil underneath forest with a depth of over 1 m to 3 m from the soil surface. And that drying layer is in great water deficit, which prevents gravitational infiltration of rainfall and replenishment of groundwater. So forests on the Loess Plateau reduced streamflow as the results of increased retention of rainfall and reduced recharge into ground water (Li, 2001; Tian, 2010). But for earth-rock mountain landscape, vegetation grows on thinner soil layer of rock mountain, which is apt to be saturated and produce soil flow on relatively impermeable rock. So the streamflow in wooded areas might be larger than that in adjacent woodless areas. Under this situation, forests may have positive impact for producing streamflow (Liu and Zhong, 1978).

To investigate that, we develop hydrological experiments based on the widely used SWAT model and observed hydrological/meteorological data and land use data in the Wei River. We aim at understanding possible impact of revegetation constructions, especially the forest restoration on streamflow and its components in the Wei River, which is not only the largest branch of the Yellow river but also with very mixed landscape with the loess plateau and earth-rock mountain. In Sect. 2, we describe the study area and data. In Sect. 3, we set up, calibrate, and validate the SWAT model in the Wei River. Section 4 reports the numerical experiment results, which is then
2. Study area and data

2.1 Study area

Wei River is the largest tributary of the Yellow River, which originates from the north of the Wushu mountain at an altitude of 3495 m (involving Gansu, Ningxia and Shaanxi Provinces), and runs across 818 km through into the Yellow River at Tongguan County, Shaanxi Province. In this study, we choose the upper and middle reaches (4.68×10^4 km^2) of the Wei River basin (103.97°~108.75° E, 33.69°~36.20° N, 13.48×10^4 km^2). And the Linjiacun, Weijiabu and Xianyang hydrological stations are used from upstream to downstream in this study (Fig. 2). Linjiacun station locates at the control section of the upstream and Xianyang station is the control station of middle reaches.

Geologically, the basin consists of the Loess Plateau and Qinling Mountain in the respective north and south of the Wei River (Fig. 2). In the north, there are fewer tributaries, whose lengths are further and the gradient is smaller. While in the south, abundant tributaries originate from Qinling Mountain which are steep and close to the river. So the tributaries are shorter and the flows are swifter. And there distribute lots of earth-rock mountain landscape and gravel riverbed in the piedmont.

2.2 Land Use and land Cover Change (LUCC) data

We obtain observed LUCC data from National Science & Technology Infrastructure of China, National Earth System Science Data Sharing Infrastructure (Fig. 3) (http://www.geodata.cn). Land use maps for the years of 1980 and 2005 were interpreted based on the corresponding national land use survey data (1:100,000), satellite image, the MODUS data, 250-meter space resolution...
data and combined with pasture resources map (1:500,000), soil type map (1:1,000,000), vegetation type map (1:1,000,000) and other auxiliary data. The LUCC data were divided into six types and further 25 subtypes. And the six types included forest, shrubland, pasture, cropland, water bodies and residential areas. The area of agricultural land decreased about 7.26% and forest area increased 0.81% in 2005 compared with 1980 for the study area.

2.3 Soil data

Soil data obtained from National Science & Technology Infrastructure of China, National Earth System Science Data Sharing Infrastructure (Fig. 4(a)) (http://www.geodata.cn). This map reflects the distribution and characteristics of different soil type and digitized based on 1:500,000 remote sensing digital figures of environment on Loess Plateau.

Based on the soil data, the distribution of earth-rock mountain in study area is drawn as Fig. 4(b). There were 83 soil types in the study area and 15 of them are composed of earth and rock involving 70 HRUs (Table 1). At the same time, these 15 soil types distribute mainly in the Qinling Mountain and Liupan Mountain (Fig. 2). And the earth-rock mountain area accounts for 24% of study area.

2.4 Meteorological and hydrological data

The meteorological data were obtained from the China Meteorological Data Sharing Service System (http://www.escience.gov.cn/metdata/page/index.html) and some additional sites from local rainfall stations. The data include atmospheric pressure, mean (minimum and maximum) temperature, vapor pressure, relative humidity, rainfall, wind speed, wind direction, sunshine time, and so on. Figure 5 (a) shows the distribution of meteorological stations and the annual average
precipitation over Wei River basin, which was calculated using kriging interpolation method of ArcGIS 9.3 based on annual average precipitation of 34 meteorological stations. Then the time series of annual average precipitation over the whole basin was calculated using Thiessen polygon method of ArcGIS 9.3, which divided the basin and gave the weight of each meteorological station according to its control area. It was 544.8 mm/yr on average varying from 267 to 920 mm (from northwest to southeast) over the past 55 years (1956-2010). The time series of rainfall over the basin was for a slight increase since 1956 and then it started to decline. After the minimum of rainfall in the 1990s, it began to increase subsequently. The annual average rainfall of 2000-2010 increased by about 6% compared with the 1990s. And the daily streamflow data of three hydrological stations came from Ecological Environment Database of Loess Plateau (http://www.loess.csdb.cn/pdmp/index.action) and the Hydrological Year books of China.

90-meter resolution digital elevation model (DEM) (Fig. 5 (b)) was used to define the topography and delineate the watershed boundary. It was obtained from the Computer Network Information Center, Chinese Academy of Sciences (http://srtm.datamirror.csdb.cn/), based on the Shuttle Radar Topography Mission (SRTM) version 4.1.

3. Methods

3.1 The SWAT model

The SWAT (Soil and Water Assessment Tool) model is developed by the USDA Agricultural Research Service (ARS). It is a physically based and distributed hydrological model. The SWAT model has been widely applied to understand the impact of land management practices on water, sediment and agricultural yields over large complex watersheds with varying soils, land use and management conditions over long periods (Arnold et al., 2009). It is forced with meteorological
data, and input with soil properties, topography, land use, and land management practices in the catchment. The physical processes associated with hydrological cycle and sediment movement etc. are directly modeled by SWAT using this input data (Arnold et al., 2009). In addition, the ArcSWAT extension (ArcSWAT 2009.93.7b version) is used as the graphical user interface for the SWAT model (Gassman et al., 2007; Arnold et al., 1998).

3.2 The SWAT Model setup

The SWAT model setup includes four steps: watershed delineation, hydrological response unit (HRU) analyst, input database building and modification and model operation. Based on research of the Wei River (Shao, 2013; Wang, 2013), the extraction threshold of subbasin area was 80 km². The Linjiacun, Weijiabu and Xianyang hydrological stations were loaded manually as subbasin outlets and one whole watershed outlet was defined. The study area was divided into 308 subbasins (Fig. 2). The land area in a subbasin can be further divided into the HRUs, which is the basic computing element of the SWAT model. In this study, a subbasin was subdivided into only one HRU that was characterized by dominant land use and soil type. Then the daily meteorological data including temperature, relative humidity, sunshine duration, wind speed, rainfall were input and all data were written into database building and modification to force the SWAT model.

For evaluating the performance in the model calibration and validation, we use the $R^2$ and NS coefficient to evaluate the performance rating of the model (Nash and Sutcliffe, 1970) (Equation (1) & (2)).

$$R^2 = \frac{\sum_{i=1}^{n} \left( \text{obs}_i - \bar{O}_i \right) \left( \text{sim}_i - \bar{O}_i \right)^2}{\sum_{i=1}^{n} \left( \text{obs}_i - \bar{O}_i \right)^2 \left( \text{sim}_i - \bar{O}_i \right)^2}$$

Eq. (1)
where \( n \) is the number of observations, \( O_{\text{obs}} \) is the observed value, \( O_{\text{sim}} \) is the simulated value, and the overbar means the average of the variable. The \( R^2 \) describes the proportion of the variance in measured data explained by the model and typically 0.5 is considered an acceptable threshold (Santhi et al., 2001; Van Liew and Garbrecht, 2003). The SWAT model simulation can be judged as “satisfactory” if the NS > 0.50 for a monthly time step simulation and the performance rating of the SWAT model was very good when the NS > 0.75, and the model performed good when the NS > 0.65 (Moriasi et al., 2007).

### 3.3 Calibration and validation of the SWAT model

We setup the SWAT-CUP procedure for the sensitivity analysis, calibration and validation in our study (Abbaspour, 2007). The sensitivity analysis is carried out by keeping all parameters constant to realistic values, while varying each parameter within the range assigned in step one. The sensitive parameters were calibrated using LH-OAT (Latin-Hypercube-One Factor-At-a-Time) method of the Sequential Uncertainty Fitting (SUFI2) program (Abbaspour, 2007; Xu et al., 2012). And the t-stat and p-value were used to evaluate the sensitivity of parameters. The t-stat is the coefficient of a parameter divided by its standard error and the larger values are more sensitive. And the p-value determines the significance of the sensitivity and a value close to zero means more significant. The most sensitive (seven) parameters were selected by the SWAT-CUP module. Combined with previous research in Wei River, two additional parameters (SOL_K and GW_DELAY) with the seven parameters were selected in this study (Table 2).
The initial value and the range of relevant parameters were derived from simulated rainfall experiments, regional monitoring data and previous research in study area. Vegetation construction changes undelaying surface and affects quantity of surface runoff and recharge of both soil and ground water. It has a significant impact on infiltration by providing canopy and litter cover to protect the soil surface from raindrop impacts and producing organic matter which can bind soil particles and increase soil porosity (Le Maitre et al., 1999). These impacts of vegetation on hydrological process were epitomized and reflected by CN and management operation in the SWAT model. The Soil Conservation Service (SCS) curve number equation is the model for computing the amounts of streamflow in SWAT model and its comprehensive parameter is CN which relates to the soil’s permeability, land use and antecedent soil water conditions. We have done some research on the impacts of LUCC changes on runoff, infiltration and groundwater under different soil, slope and rainfall intensity in Wei River basin based on simulated rainfall experiments before (Wang, 2014). Based on the experiments, the SCS model and the three-dimensional finite-difference groundwater flow model (MODFLOW) were calibrated and applied also. So values of parameters related to runoff, infiltration and groundwater, such as the initial CN values and recharge rates for different LUCC, specific yield of soil layer etc. were gotten based on experiments and mathematical simulation (Wang, 2014). Meanwhile in the SWAT model, agricultural land and forest have different heat units required for plant maturity and different management operations. The agricultural land includes plant, harvest / kill and auto-fertilizer operation and the forest only has plant operation. And the management operation of forest involves leaf area index (LAT_INIT), plant biomass (BIO_INIT), age of trees (CURYR_MAT) and so on.
According to Fig. 1, we could see the revegetation was mainly implemented in the study area after the 1980s. Hence we choose 1960-1969 and 1970-1979 for the model calibration and validation respectively and use the daily streamflow data of the Linjiacun, the Weijiabu and the Xianyang hydrological stations from the upper to middle reaches (in the Weijiabu station, the data of 1965 and 1968-1971 are missing). The parameters were calibrated for hydrological stations by the order of upstream to downstream using the daily streamflow of 1960-1969. Firstly, the parameters against the streamflow at the Linjiacun control station were calibrated. Secondly, based on the premise of the calibrated parameter values of the Linjiacun station, the parameters were calibrated for the subbasin controlled by the Weijiabu station. In that way, the parameters for the subbasin controlled by the Xianyang station were then calibrated.

4. Results and discussions

Then the SWAT model was validated for the three hydrological stations respectively against the streamflow from 1970 to 1979 (Fig. 6). The statistic results showed that the ranges of NS and $R^2$ were 0.59–0.66 and 0.63–0.68 respectively in the calibration period for a daily time step. And they were 0.57–0.62 and 0.61–0.65 respectively in the validation period. At a monthly time step, the results of the NS and $R^2$ were 0.82–0.84 and 0.79–0.86 respectively in the calibration period. And they were 0.70–0.76 and 0.74–0.79 respectively in the validation period demonstrating good performance of the model. In addition, the time-series and the pattern of the simulated and observed streamflow during the calibration period and validation period showed similar trends. Our conclusion is that the SWAT model can be used in upper and middle reaches of the Wei River basin.

4.1 Impact of the observed LUCC on streamflow
In order to analyze the impact of the LUCC on streamflow, the land use data of the 1980 and 2005 were used in the validated SWAT model. Firstly, the daily streamflow from 1980 to 2009 were simulated using observed daily meteorological forcing data and topography, soil data and so on. Secondly, the LUCC data of 1980 was replaced by that of 2005 and their relevant parameters of corresponding land use type were also replaced. We use the LUCC data of 2005 but the same meteorological data to simulate the daily streamflow from 1980 to 2009.

The change of annual streamflow based on LUCC data of 2005 compared with LUCC data of 1980 showed that annual streamflow decreased during 20 years and the annual average reduction was 94 million m$^3$ for these years. This is mainly because over different land use types hydrological responds differently even to the same meteorological forcings. For example, rainfall intensity is of great importance influencing to hydrological process of the Wei River, which locates in semi-dry and semi-humid region. Results of rainfall numerical experiments showed when the rainfall intensity was smaller or larger, the rainfall would infiltrate into soil or flow away as surface runoff mainly on both grass land and bare slope, while when the rainfall intensity was medium, the rainfall would infiltrate into grass land and flowed away as surface runoff on bare slope (Tobella et al., 2014; Wang, 2014). To reduce influence of meteorological condition and isolate the impact of the LUCC on streamflow, 30-year average of the streamflow for forest and agricultural land were taken, respectively. Figure 7 shows changes of streamflow, surface runoff, soil flow and baseflow between agricultural land and forest. The surface runoff, soil flow and baseflow all decreased for agricultural land, while the soil flow and baseflow of forest increased.

Overall, the streamflow decreased in agricultural land and increased in forest area.

4.2 Hydrological experiments on the impact of conversion of
Because the LUCC data involves various land use interconversions, of particular interest here the impact of conversion of cropland to forest on streamflow cannot be distinguished. Starting from the LUCC data of 1980 as (S1) the present land use, we design other four scenarios (Table 3) that (S2) 10%, (S3) 20%, (S4) 40% and (S5) 100% of the agricultural land was converted into forest respectively. Based on the five scenarios, the SWAT simulation was conducted to analyze the effect of forest constructions on the streamflow in upper and middle reaches of the Wei River basin. Firstly, the converted agricultural land area was controlled proportionately as same as the variational area ratios of set scenarios in 3 regions. Secondly, lands with the same soil type and similar slope were the priorities choosing as the converted land. Thirdly, the converted lands were distributed evenly as much as possible in 3 regions. The simulation was from 1980 to 2009.

We present the distribution of average streamflow change under S2 ~ S5 scenarios compared with S1 scenario in Fig. 8. It shows that the streamflow generally increased when the land use converted from agricultural land into forest in the upstream. And Fig. 9 shows the corresponding proportional change rate of streamflow at the Linjiacun, Weijiabu and Xianyang stations for its annual average and annual average over non-flood season (Jan - Jun and Nov - Dec). Compared with the S1 scenario, the annual average streamflow increases in the non-flood season were 12.70%, 11.21% and 9.11% for the Linjiacun, Weijiabu and Xianyang stations with per 10% area of agricultural land converted into forest. Interestingly the average annual streamflow increases were 11.61%, 21.63%, 42.51% and 109.25% for S2, S3, S4 and S5 scenario respectively (Fig. 9 (b)), which almost consistently suggest about 1.1% per 1% change of the agricultural land. The results are important in that one can expect that for a 0.8% increase in the forest in the observed
LUCC would lead to less than 1% change in the streamflow, which is negligible.

To be more comparable, Fig. 10 shows the distribution of the annual runoff coefficient with the scenario changed from S1 to S5. The spatial variability in mean runoff coefficient is large, which ranges from 0.03 to 0.68 and increased with more forest converted from agricultural land. The annual average runoff coefficient of study area increased from 0.21 to 0.37 with forest area increasing from S1 to S5 (Fig. 11). On average, the runoff coefficient increased about 0.014 (i.e., 1.4% of rainfall transformed into streamflow) with per 10% area of agricultural land converted into forest.

The landscape of the Wei River is mixed with the Loess Plateau and earth-rock mountain landscapes, which induce different mechanisms of transforming rainfall into streamflow. The earth-rock mountain area accounts for 24.03% of study area (Fig. 4 (b)). In earth-rock mountain area, vegetation grows on much thinner soil layer over the earth-rock mountain. The thin soil is apt to be saturated and produce more soil flow on relatively impermeable rock, hence the streamflow in wooded areas is larger than that in adjacent woodless areas favoring streamflow production (Liu and Zhong, 1978). On the contrary, in Loess Plateau there is exiting a drying layer of soil underneath forestland in great water deficit. Together with much thicker soil layer on the Loess Plateau, it usually prevents gravitational infiltration into groundwater and reduces streamflow recharge (Li, 2001; Tian, 2010). So the complication is that the overall effect of forest on the streamflow is in fact a balance between earth-rock mountain positive and Loess Plateau negative effects on the streamflow.

Combined with the spatial distribution of precipitation (Fig. 5 (a)), we can see earth-rock mountain landscapes are mainly distributed in regions with more rainfall. To be precise, the whole
earth-rock mountain area located where rainfall was greater than 500 mm/yr and over 62% of the study area where the annual rainfall is greater than 600 mm was in earth-rock mountain. Meanwhile, the river network over the earth-rock mountain is denser and most of tributaries in the earth-rock mountain are close to the main stream of the Wei River. Moreover, there distribute a lot of developed gravel riverbed in piedmont, sandy soil along the river and its groundwater level is shallow, which facilitate rainfall infiltration and recharging streamflow. Therefore although the area of earth-rock mountain accounts for 24% of the study area, its distribution areas are concentrated in the main regions of streamflow yield of the study area. Therefore the overall result of balance among all factors was that the forest constructions have positive effect on streamflow.

4.3 Impact of conversion of agricultural land to forests on baseflow

In Fig. 9 (a), one important point is that the average increase in the non-flood season was about 1.41 times larger than the annual increase of the streamflow. To understand that, Fig. 12 shows distribution of the baseflow index, i.e., the ratio between baseflow and streamflow, under S1–S5 scenarios. We can see that the baseflow index also increased with land use converted from agricultural land into forest, which means that groundwater contribution to the streamflow increased with the overall increase of forest area. Putting the picture together, Fig. 13 shows the changes of the streamflow and the baseflow under the S2–S5 scenarios minus those under the S1 scenario for annual average streamflow and the baseflow in the non-flood season. The average increasing of streamflow and baseflow were 1.14 and 0.98 mm/yr with per 1% increase of forest area respectively. For the non-flood season, they were 0.60 and 0.53 mm. The increase of the streamflow contributed by the increased baseflow was about 88.33% in the non-flood season. So the increasing streamflow was mainly contributed by groundwater with increasing of forest area.
The large scalar implementation of Grain for Green project in China is expected to alter hydrological cycle, in particular on the Loess Plateau, within the Yellow River Basin. The scientific question is how large the impact of the LUCC on the streamflow and its components in that area. We choose the Wei River as the study area, in that it has been widely implemented revegetation constructions since the 1980s. Of particular interest here, the landscape of the upper and middle reaches of the Wei River basin is mixed with the Loess Plateau and rocky mountain, which would induce different mechanisms of generating surface runoff, soil flow, base flow and therefore streamflow.

To investigate it, we setup the SWAT model for the upper and middle reaches of the Wei River basin with the inputs of long term observed meteorological forcing data, hydrological data, and observed land use data. We use daily and monthly streamflow of the Linjiacun, Weijiabu and Xianyang hydrological stations from upper to middle reaches during 1960-1969 and 1970-1979 respectively for the model calibration and model validation. The results showed that the Nash-Sutcliffe (NS) coefficients and the coefficients of determination ($R^2$) were $> 0.57$ and 0.61 for daily streamflow and 0.70 and 0.74 for monthly streamflow respectively demonstrating that the SWAT model can be used in this study.

We analyse the impact of the LUCC on streamflow based on the observed LUCC data of 1980 and 2005. The daily streamflow from 1980 to 2009 were simulated using observed daily meteorological data with the two different land use data. The results showed that two-thirds of annual streamflow decreased and the change of streamflow was different among different land use.
On the overall average, the 30-year averages of the streamflow decreased in agricultural land but increased in forest. To interpret the overall result, we design five scenarios in this study including (S1) the present land use of 1980 and the scenarios where agricultural land was converted into forest by 10% (S2), 20% (S3), 40% (S4) and 100% (S5) respectively. Based on the five scenarios, we use the calibrated and validated SWAT model to analyze the effect of forest constructions on the streamflow in detail. The results confirm that annual streamflow consistently increased with more forest converted from the agricultural land. Interestingly, the rate is almost consistently 7.41 mm/yr per 10% increase of forest converted from the agricultural land. Based on detailed analysis of each component of streamflow, we found it was most attributed by the baseflow. The overall effect of LUCC on the streamflow in the Wei River basin, the largest branch of the Yellow River is the result of the balance between Loess Plateau negative and earth-rock mountain positive effects. Our results here are not only of great importance in understanding the impact of LUCC on streamflow for a catchment with much complicated and mixed landscape, but also of significance for water resources managing practice.

**Data availability**

The data used in this manuscript were obtained from reliable public data repositories. The LUCC and soil data were obtained from the National Science & Technology Infrastructure of China, the National Earth System Science Data Sharing Infrastructure (http://www.geodata.cn). The DEM data were obtained from the Computer Network Information Center, the Chinese Academy of Sciences (http://srtm.datamirror.csdb.cn/). The meteorological data were obtained from the China Meteorological Data Sharing Service System (http://www.escience.gov.cn/metdata/page/index.html). The daily streamflow data were from the
Ecological Environment Database of Loess Plateau (http://www.loess.csdb.cn/pdmp/index.action) and the Hydrological Yearbooks of China.

Acknowledgment

This research was supported by an Open Research Fund of State Key Laboratory of Desert and Oasis Ecology, Xinjiang, Institute of Ecology and Geography, Chinese Academy of Sciences, CPSF-CAS Joint Foundation for Excellent Postdoctoral Fellows, the Chinese Academy of Sciences (CAS) Pioneer Hundred Talents Program. We thank the Editor and reviewers for valuable comments that improved the manuscript.

Notes: ① Agricultural land refers to the land for crops planting, including cultivated land, newly cultivated soil, fallow field, rotation plot, pasture-crop rotation and land used for agro-fruit, agro-mulberry, agroforestry (The code in model is AGRL). ② Forest refers to the natural forest and plantation, which canopy density is larger than 30%, including timberland, economic forest, protection forest (The code in model is FRST).
