Dear Reviewer,

Thank you for your useful revision and remarks. Please find enclosed our reply to your interactive comment on the manuscript "Simple Scaling of Extreme Precipitation in North America" published in HESSD. We provide below a detailed response to each of your comments (which are reported in red in the following text) and a copy of the revised manuscript in "track changes" mode in which specific colours are used to link corrections to reviewers’ comments. In particular, in the "track changes" manuscript,

– red$^{R2}$ is used to underline changes related to your comments,
– while blue$^{R1}$ is used for changes related to the first referee’s comments [see the HESS interactive discussion web-page],
– and green is used for other changes.

Line numbering (in bold) refers to the revised manuscript with "track changes" attached to this reply.

Sincerely,

Silvia Innocenti, on behalf of the co-authors.
The article is well written and mainly clear. There is a substantial amount of work and many interesting results. However

1) Although Sections 1 and 2 are very clear, I had at first reading some difficulties understanding the rest of the paper, mainly because I got confused with the concepts of “d1” and “interval length”. For example, if I understood correctly, an interval length of 6 durations with d1=1h for SD corresponds to durations 1h, 1h15, . . ., 2h30, whereas an interval length of 6 durations with d1=1h for ID corresponds to durations 1h, 2h, . . ., 6h. This may be confusing, so the authors may want to clarify these concepts, maybe giving examples or a table with the different intervals.

We apologize for this lack of clarity, which was also pointed out by the first referee [see our reply to comment 1a) of the first reviewer]. To improve the description of the set of scaling intervals and their characteristic d1 (initial duration), length (number of durations considered), and time-step (the time-increment separating contiguous durations within each dataset, equal to 15min in SD, 1h in ID, and 6h in LD) we modified the paragraph describing these characteristics to [Lines 27 to 5, Page 7]:

"In order to identify possible changes in the SS properties of AMS distributions, various scaling intervals were defined for the MSA. In particular, all possible subsets with 6, 12, 18 and 24 contiguous durations were considered within each dataset. Figure 1 and Figure 2 show the 136 scaling intervals thereby defined: 40 scaling intervals for SD and IS, and 56 scaling intervals for LD. For instance, the first matrix on the left of Fig. 1(a) presents the 6-duration scaling intervals 15 min - 1.5 h, 30min - 1.75h, . . ., 4.75 h - 6 h defined for the SD dataset [i.e. the 19 scaling intervals containing six contiguous durations defined with a 15min increment], while Fig. 1(d) shows an example of the first four 6-duration scaling intervals for the ID dataset [i.e. 1 h - 6 h, 2 h - 7 h, 3 h - 8 h, and 4 h - 9 h, containing six contiguous durations defined with an increment of 1h]. This procedure was defined in order to evaluate the sensitivity of the SS estimates to changes in the first duration d1 of the scaling interval and in the interval length [i.e. the number of durations included in the scaling interval]."

2) The authors use databases with different measurement frequencies. So I expect, e.g., the 1h-annual maxima at a given location to be larger when they stem from accumulating 15min rainfall than hourly rainfall. Thus I’m concerned about all the comparisons mixing these different measurement frequencies: do we expect H for example to be the same for different measurement frequencies? Likewise for the GEV parameters. In a pretty related study, Blanchet et al 2016 addresses this issue.

We agree that the temporal resolution of observed series, as well as the measurement resolution of rain gauges, may have an impact on the estimations of the AMS and of the scaling exponents.

Note however, that for many stations both DMPD and HCPD, or both 15PD and HPD series are available over a common period [note also that the names of the 4 datasets have been changed according to your minor comment 4)]. For these stations, annual maxima measured at the two different temporal resolutions were compared and combined [for each year, the annual maximum value of the two AMS was retained] In this way, the impact of the temporal resolution should have been partially reduced. [note that, to improve the description of this preliminary step in the construction of our AMS Lines 17 to 20, Page 7 have been rephrased. Please, see our reply to minor comment 5)].

At the same time, the double resolution effects [temporal and measurement resolution effects which could add and have a greater impact on shortest durations] may still affect the estimation of AMS Simple Scaling. In fact, some of these issues have been raised and briefly discussed while analysing GOF test results [see Lines 17 to 23, Page 10]. Some complementary analyses have also been presented in the supplementary material, Sect. S2 and Fig. S2-S3. [Note that, for completeness, we added the reference to Blanchet et al (2016) at Line 23, Page 10].
However, despite the obvious interest of studying the effects of these factors, it would have been difficult, with the available datasets, to separate the influence of the temporal and measurement resolutions on extreme precipitation inference from the effect of other factors, such as, sampling errors associated to the series length. Moreover, pooling the four datasets allow the construction of a rainfall dataset with an exceptional extent and density for North America. Hence, we decided to use these four datasets to construct the three AMS dataset SD, ID, and LD which constitute a remarkable data source for the study of Simple Scaling of extreme precipitation at a regional scale.

For completeness, however, the following comment has been added to the Conclusion [Line 6, Page 18]:

"... and (these results) show the importance of a deeper analysis to evaluate the impact of dataset characteristics (e.g., their temporal and measurement resolutions, or the series length) on the scale invariant properties of extreme precipitation."

Detailed Comments

1  p.3 l.5 “a deeper analysis . . . needed”: Blanchet et al 2016 make such a regional analysis in South of France. The study region is much smaller but rainfall variability seems quite comparable. The reference has been added at Line 4, Page 3.

2  p.4 l.11 “H_{intensity} and H_{depth}”: not defined

   The sentence has been rephrased in order to add the explicit definition of $H_{depth}$ [Line 20, Page 4]:

   "(note that for the rainfall depth the scaling exponent $H_{depth} = 1 - H$ applies)."

3  section 2.2: Blanchet et al. 2016 use a GEV-ML estimation in a single step.

   The following paragraph has been moved from Sect. 6 to Line 5, Page 6 [Sect. 2] in order to clarify that a one-step procedure can also be used for the estimation of the SS-GEV parameters:

   "In a few other cases, a Generalized Additive Model ML (GAM-ML) framework (Coles, 2001; Katz, 2013) has also been used to obtain the joint estimate of $H, \mu, \sigma, \xi$ through the introduction of the duration as model covariate (e.g., Blanchet et al, 2016)."

   Note that this procedure has been tested in our preliminary analyses, as mentioned at Lines 27 to 30, Page 15. Please, see also our reply to minor comment 12.

4  section 3: it may be clearer for the reader to call the 4 databases 15PD, H1PD, H2PD and DPD.

   As suggested, we homogenized the dataset acronyms changing DM to DMPD and H to HCPD [Line 9, Page 6 and following paragraphs]. However, we kept the acronyms "HPD" and "15PD" for US datasets since these are the official acronyms used by the NOAA [http://www.ncdc.noaa.gov/data-access/land-based-station-data].

5  p.6 l.20: so if I understand correctly SD comprises stations from 15PD only, ID from both 15PD and HPD, and LD from both 15PD, 1HPD and DPD (DPD only for the duration intervals >=1day). I’m correct? The authors may want to clarify it. In which case, the authors are analysing annual maxima with different measurement frequencies, without taking this at all into account. I wonder how the results/parameters you’re comparing later are really comparable.
We apologize for this lack of clarity but the stations included within each of the SD, ID, and LD dataset were selected according to a procedure slightly different from the one you mentioned. In particular, while it is correct that the SD dataset uses 15PD data only, both ID and LD datasets use all relevant series to construct AMS for the sampled durations [Please, see also Tables 1 and 2, and reply to major comment 2). To improve the description of dataset construction Lines 17 to 20, Page 7 have been modified to:

(iv) For each selected station, annual maxima were extracted for each valid year and duration. For stations having both DMPD and HCPD series, or 15PD and HPD series, for each year, the annual maxima extracted from these two series were compared and the maximum value was retained as the annual maximum for that year.

Moreover, we agree that the inhomogeneity of the series temporal resolution should be taken into account when interpreting our results, as well as other factors such as the different series length, measurement resolution, etc [Please, refer to the reply to major comment 2). However, it is a priori difficult to assess and separate the impacts of each of these inhomogeneities on the SS estimation. In particular, in our opinion, it is difficult to rigorously relate one or some of these inhomogeneities to any specific feature observed for the H distribution or GEV parameters. Hence, we assumed that they will not globally nor significantly affect our results nor the main conclusions of our study. For completeness, however, a brief comment about this issue has been added in the Conclusion [see Line 6, Page 18 and major comment 2].

6 p.6 l. 23-26: Papalexiou and Koutsoyannis 2013 and Blanchet et al. 2016 consider also the rank of the observed maxima to decide whether they should consider it or not in the analysis.

As in Papalexiou and Koutsoyiannis (2013), the following criterion was used: for each series, observation that are at least one order of magnitude larger than the series second largest value were excluded. This procedure was repeated until the ratio between the two largest values of the series was less than an order of amplitude. This detail, as well as your suggested reference, has been added at Line 7, Page 7:

"Note that, in order to exclude outliers possibly associated with recording or measurement errors, extremely large observations were discarded and assimilated to missing data. In particular, as in some previous studies (e.g., Papalexiou and Koutsoyiannis, 2013; Papalexiou et al., 2013), an iterative procedure was applied prior to step (ii)-1) to discard observations larger than 10 times the second largest value of the series."

7 p.8 l. 8: I don’t understand what are the “SS” and “non-SS” samples.

The definitions of SS and non-SS samples have been added at Line 27, Page 8:

"As in previous applications (e.g., Panthou et al., 2014), the AD and KS tests were then applied at significance level $\alpha = 0.05$ to compare the empirical distributions (Cunnane plotting formula, Cunnane, 1973) of the SS sample, $x_{d,ss} = d^{-H} x_{d*}$, and the non-SS sample, $x_d$."

Then, we rephrased the sentence at Line 16, Page 9 as:

"According to this approach, data in $x_d$ and $x_{d,ss}$ were pooled and randomly reassigned to two samples having same sizes of the SS and non-SS samples."

8 Figures 1 and 2: it took me time to understand these figures, partly because the x-axis are not labeled. Please add the labels (d1?).

Done.
9 Figure 3: isn’t there also an effect of measurement frequency in the plots for ID and LD?

We would appreciate the reviewer be more specific and explain how she concluded that an affect of measurement frequency can be seen in Figure 3. In our opinion, further analyses would be needed to evaluate this effect, as previously mentioned. Please, see also our replies to major comment 2) and minor comment 5).

10 section 6: do I understand correctly that “non-SS” cases mean that the GEV parameters are estimated using the data from d* only? Please make it clearer.

We apologize for this lack of clarity but the non-SS GEV parameters were not estimated using the data from d* only: for each duration d, non-SS GEV parameters were estimated on the non-SS sample $x_d$, independently from other durations. To clarify this point, Lines 24 to 27, Page 15 have been modified to:

"In our study, the PWM procedure was applied to estimate SS-GEV parameters $\mu_*, \sigma_*$, and $\xi_*$ [Eq. (7)] from $x_{d*}$ [Eq. (8)]. For each duration d, PWM were also used to estimate non-SS parameters $\mu_d$, $\sigma_d$, and $\xi_d$ from each of the non-SS samples $x_d$."

11 Figure 4: it might be clearer for comparison to use the same US map for the three rows (the first row is different so far). Also there might be here an effect of the measurement frequency for LD and ID, although the spatial patterns are pretty coherent.

When using the same map limits for all maps of Fig. 4 and 5, the nine maps becomes really small while a lot of blank space is present in the first row because there are no stations in Canada and Alaska. The figure is thus less clear when the same latitude and longitude limits are used for the nine maps. Moreover, since the focus is the comparison of the maps placed in the same row (i.e., in the same dataset), we prefer to keep the map limit for SD as they are now.

Concerning the eventual effect of the measurement frequency, please see replies to major comment 2) and minor comments 5) and 9). We agree that spatial patterns are fairly homogeneous suggesting that the series temporal resolution has a weak impact on the estimation of H.

12 Figure 5: same as Fig. 4.

Please, see the reply to the previous comment.

30 p.13 l.26: So if I understand correctly, here you use the H estimated previously and estimation is just for the GEV parameters. Please make it clearer. Have you also tried to estimate all parameters at once (mu*, sigma*, xi*, H) with ML estimators as in Blanchet et al 2016 for example? Theoretically, this should reduce the bias.

Yes, SS-GEV $\mu_*$, $\sigma_*$, and $\xi_*$ presented in our results are estimated applying PWM on the rescaled sample $x_{d*}$ [i.e. using a two-step procedure, as described at Lines 1 to 5, Page 6]. To address the reviewer’s comment, we rephrased Lines 24 to 27, Page 15 as reported in our reply to minor comment 10.

The one-step procedure of Blanchet et al (2016) has also been tested. To point this out, the relevant paragraph has been rephrased as [Lines 27 to 30, Page 15]:

"Preliminary comparisons of various estimation methods [PWM, classical ML estimators, and one-step GAM-ML; see Sect. 2.2], showed that PWM slightly outperformed the other methods".
13 Figure 9: isn’t there also an effect of measurement frequency in the plots for ID and LD?

Please, see our reply to previous comments, in particular reply to major comment 2) and minor comments 5) and 11).

14 Figure 10: idem

5 Please, see our reply to the previous comment.

15 Figure 11: please add in the legend “with Hosking test at level 5%”

Done.

Simple Scaling of extreme precipitation in North America

Abstract. Extreme precipitation is highly variable in space and time. It is therefore important to characterize precipitation intensity distributions at several temporal and spatial scales. This is a key issue in infrastructure design and risk analysis, for which Intensity-Duration-Frequency (IDF) curves are the standard tools used for describing the relationships among extreme rainfall intensities, their frequencies, and their durations. Simple Scaling (SS) models, characterizing the relationships among extreme probability distributions at several durations, represent a powerful means for improving IDF estimates. This study tested SS models for approximately 2700 stations in North America. Annual Maxima Series (AMS) over various duration intervals from 15 min to 7 days were considered. The range of validity, magnitude, and spatial variability of the estimated scaling exponents were investigated. Results provide additional guidance for the influence of both local geographical characteristics, such as topography, and regional climatic features on precipitation scaling. Generalized Extreme Value (GEV) distributions based on SS models were also examined. Results demonstrate an improvement of GEV parameter estimates, especially for the shape parameter, when data from different durations were pooled under the SS hypothesis.

1 Introduction

Extreme precipitation is highly variable in space and time as various physical processes are involved in its generation. Characterizing this spatial and temporal variability is crucial for infrastructure design and to evaluate and predict the impacts of natural hazards on ecosystems and communities. Available precipitation records are however sparse and cover short time periods, making a complete and adequate statistical characterization of extreme precipitation difficult. The resolution of available data, whether observed at meteorological stations or simulated by weather and climate models, often mismatches the resolution needed for applications (e.g., Blöschl and Sivapalan, 1995; Maraun et al., 2010; Willems et al., 2012), thus adding to the difficulty of achieving complete and adequate statistical characterizations of extreme precipitation.

The need for multi-scale analysis of precipitation has been widely recognized in the past (Rodriguez-Iturbe et al., 1984; Blöschl and Sivapalan, 1995; Hartmann et al., 2013; Westra et al., 2014, among others) and much effort has been put into the development of relationships among extreme precipitation characteristics at different scales. The conventional approach for characterizing scale transitions in time involves the construction of Intensity-Duration-Frequency (IDF) or the equivalent Depth-Duration-Frequency (DDF) curves (Bernard, 1932; Burlando and Rosso, 1996; Sivapalan and Blöschl, 1998; Koutsoyiannis et al., 1998; Asquith and Famiglietti, 2000; Overeem et al., 2008; Veneziano and Yoon, 2013). These curves are a standard tool for hydraulic design and risk analysis as they describe the relationships between the frequency of occurrence of
extreme rainfall intensities (depth) $X_d$ and various durations $d$ (e.g., CSA, 2012). Analysis is usually conducted by separately estimating the statistical distributions of $X_d$ at the different durations (see Koutsoyiannis et al., 1998; Papalexiou et al., 2013, for discussions about commonly used probability distributions). The parameters or the quantiles of these theoretical distributions are then empirically compared to describe the variations of extreme rainfall properties across temporal scales.

Despite its simplicity, this procedure presents several drawbacks. In particular, it does not guarantee the statistical consistency of precipitation distributions, independently estimated at the different durations, and it limits IDF extrapolation at non-observed scales or ungauged sites. Uncertainties of estimated quantiles are also presumably larger because precipitation distribution and IDF curve parameters are fitted separately.

Scaling models (Lovejoy and Mandelbrot, 1985; Gupta and Waymire, 1990; Veneziano et al., 2007) based on the concept of scale invariance (Dubrulle et al., 1997), have been proposed to link rainfall features at different temporal and spatial scales. Scale invariance states that the statistical characteristics (e.g., moments or quantiles) of precipitation intensity observed at two different scales $d$ and $\lambda d$ can be related to each other by a power law of the form:

$$f(X_{\lambda d}) = \lambda^{-H} f(X_d)$$

where $f(.)$ is a function of $X$ with invariant shape when rescaling the variable $X$ by a multiplicative factor $\lambda$ and for some values of the exponent $H \in \mathbb{R}$. In the simplest case, a constant multiplicative factor adequately describes the scale change.

The corresponding mathematical models are known as Simple Scaling (SS) models (Gupta and Waymire, 1990). SS models are attractive because of the small number of parameters involved, as opposed to multiscaling (MS) models which involve more than one multiplicative factor in Eq. (1) (e.g., Lovejoy and Schertzer, 1985; Gupta and Waymire, 1990; Burlando and Rosso, 1996; Veneziano and Furcolo, 2002; Veneziano and Langousis, 2010; Langousis et al., 2013). A single scaling exponent $H$ is used to characterize the extreme rainfall distribution at all scales over which the scale invariance property holds. As a consequence, a consistent and efficient estimation of extreme precipitation characteristics is possible, even at non-sampled temporal scales, and a parsimonious formulation of IDF curves based on analytical results is available (e.g., Menabde et al., 1999; Burlando and Rosso, 1996; De Michele et al., 2001; Ceresetti, 2011).

Theoretical and physical evidence of the scaling properties of precipitation intensity over a wide range of durations has been provided by several studies. MS has been demonstrated to be appropriate for modeling the temporal scaling features of the precipitation process (i.e., not only the extreme distribution) and for the extremes in event-based representations of rainfall (stochastic rainfall modeling) (e.g., Veneziano and Furcolo, 2002; Veneziano and Iacobellis, 2002; Langousis et al., 2013, and references therein). These multifractal features of precipitation last within a finite range of temporal scales (approximatively between 1 hour and 1 week) and concern the temporal dependence structure of the process. They have been connected to the large fluctuations of the atmospheric and climate system governing precipitation which are likely to produce a "cascade of random multiplicative effects" (Gupta and Waymire, 1990).

At the same time, many studies confirmed the validity of SS for approximating the precipitation distribution tails in IDF estimation (for examples of durations ranging from 5 min to 24 h see Menabde et al., 1999; Veneziano and Furcolo, 2002; Yu et al., 2004; Nhat et al., 2007; Bara et al., 2009; Ceresetti et al., 2010; Panthou et al., 2014). This type of scaling is substantially
different from the temporal scaling since it only refers to the power law shape of the marginal distribution of extreme rainfall. Application of the SS models to precipitation records showed that the scaling exponent estimates may depend on the considered range of durations (e.g., Borga et al., 2005; Nhat et al., 2007) and the climatological and geographical features of the study regions (e.g., Menabde et al., 1999; Bara et al., 2009; Borga et al., 2005; Ceresetti et al., 2010, Blanchet et al., 2016). However, the application of the SS framework has been mainly restricted to specific regions and small observational datasets. A deeper analysis of the effects of geoclimatic factors on the SS approximation validity and on estimated scaling exponent is thus needed.

The present study aims to deepen the knowledge of the scale-invariant properties of extreme rainfall intensity by analyzing SS model estimates across North America using a large number of station series. The specific objectives of this study are: a) assess the ability of SS models to reproduce extreme precipitation distribution; b) explore the variability of scaling exponent estimates over a broad set of temporal durations and identify possible effects of the dominant climate and pluviometric regimes on SS; c) evaluate the possible advantages of the introduction of the SS hypothesis in parametric models of extreme precipitation.

The article is structured as follows. In Sect. 2 the statistical basis of scaling models is presented, while data and their preliminary treatments are described in Sect. 3. Sect 4 presents the distribution-free estimation of SS models and their validation using available series. Section 5 focuses on the spatial variability of SS exponents and discusses the scaling exponent variation from a regional perspective. Finally, the SS IDF estimation based on the Generalized Extreme Value (GEV) assumption is discussed in Sect. 6, followed by a discussion and conclusions [Sect. 7].

2 Simple Scaling models for precipitation intensity

When the equality in Eq. (1) holds for the cumulative distribution function (cdf) of the precipitation intensity $X$, considered at two different durations $d$ and $\lambda d$, $X_{\lambda d} \overset{d}{=} \lambda^H X_d$, Simple Scaling can be expressed as (Gupta and Waymire, 1990; Menabde et al., 1999):

$$X_d \overset{d}{=} \lambda^H X_{\lambda d},$$

$$X_\lambda \overset{d}{=} \lambda^{-H} X_d R_1.$$ (2)

where $H \in \mathbb{R}$ and $\overset{d}{=} \lambda^H$ means that the same probability distribution applies for $X_d$ and $X_{\lambda d}$, up to a dilatation or contraction of size $\lambda^H \lambda^{-H} = (D/d)^{-H} R_1$. An important consequence of the SS assumption is that, if $X_d \overset{d}{=} X_\lambda R_1$ has finite moments $E[X_d^q] = E[X_\lambda^q R_1]$ of order $q$, then $X_d \overset{d}{=} X_\lambda R_1$ and $\lambda^H X_{\lambda d} \overset{d}{=} X_d R_1$ have the same distribution. Their moments are thus linked by the following relationship (Gupta and Waymire, 1990; Menabde et al., 1999):

$$E[X_d^q] = \lambda^{Hq} E[X_{\lambda d}^q].$$

$$E[X_\lambda^q] = \lambda^{-Hq} E[X_d^q].$$ (3) R_1

30
This last relationship is usually referred to as the *wide sense* simple scaling property (Gupta and Waymire, 1990) and signifies that simple scaling results in a simple translation of the log-moments between scales:

\[
\ln \{E[X_d^q]\} = \ln \{E[X_{d^*}^q]\} + Hq \ln \lambda \tag{4}
\]

\[
\ln \{E[X_D^q]\} = \ln \{E[X_{d^*}^q]\} - Hq \ln \lambda \tag{4} \tag{R1}
\]

Moreover, without loss of generality, \( \lambda \) can always be expressed as the scale ratio \( \lambda = d/d^* \) defined for a reference duration \( d^* \) chosen, for simplicity, as \( d^* = 1 \). Therefore, the SS model can be estimated and validated over a set of durations \( d_1 < d_2 < \ldots < d_D \) by simply checking the linearity in a log-log plot of the \( X \) moments versus the observed durations \( d_j, j = 1, 2, \ldots, D \), the scale ratio \( \lambda \) in a log-log plot [see, for instance, Gupta and Waymire (1990); Burlando and Rosso (1996); Fig. 1 of Nhat et al. (2007); and Fig. 2 (a) of Panthou et al. (2014)].

If \( H \) estimated for the first moment equals the exponents (slopes) for the other moments, the precipitation intensity \( X \) can be considered scale invariant under SS in the interval range of durations \( d_1 \) to \( d_D \).

More sophisticated methods have also been proposed for detecting and estimating scale invariance (for instance, dimensional analysis, Lovejoy and Schertzer (1985); Tessier et al. (1993); Bendjoudi et al. (1997); Dubrulle et al. (1997); spectral analysis and wavelet estimation Olsson et al. (1999); Venugopal et al. (2006); Ceresetti (2011); and empirical probability distribution function (pdf) power law detection Hubert and Bendjoudi (1996); Sivakumar (2000); Ceresetti et al. (2010)). However, estimation through the moment scaling analysis is by far the simplest and most intuitive tool to check the SS hypothesis for a large dataset. For this reason, the presented analyses are based on this method.

According to the literature, the values of the scaling exponents \( H \) generally range between 0.4 and 0.8 for precipitation intensity considered at daily and shorter time scales (e.g., Burlando and Rosso, 1996; Menabde et al., 1999; Veneziano and Furcolo, 2002; Bara et al., 2009) (note that for the rainfall depth the scaling exponent \( H_{depth} = 1 - H \) applies). Values from 0.3 to 0.9 have also been reported for some specific cases (e.g., Yu et al., 2004; Panthou et al., 2014, for scaling intervals defined within 1 h and 24 h).

Higher \( H \) values have been generally observed for shorter-duration intervals, and regions dominated by convective precipitation (e.g., Borga et al., 2005; Nhat et al., 2007; Ceresetti et al., 2010; Panthou et al., 2014, and references therein). Nonetheless, some studies performing spatio-temporal scaling analysis reached a different conclusion. For instance, Eggert et al. (2015), analyzing extreme precipitation events from radar data for durations between 5 min and 6 h and spatial scales between 1 km and 50 km, indirectly showed that stratiform precipitation intensity generally displays higher temporal scaling exponents than convective intensity. For short-duration intervals (typically less than one hour), previous studies have also reported more spatially homogeneous \( H \) estimates than for long-duration intervals (e.g., Alila, 2000; Borga et al., 2005, and references therein). This suggests that processes involved in the generation of local precipitation are comparable across different regions.

More generally, higher \( H \) values are associated with larger variations in moment values as the scale is changed (i.e. a stronger scaling), while \( H \) close to zero means that the \( X_d \) distributions for different durations \( d \) more closely match each other.
2.1 Simple Scaling GEV models

Annual Maximum Series (AMS) are widely used to select rainfall extremes from available precipitation series. Various theoretical arguments and experimental evidences support their use for extreme precipitation inference (e.g., Coles et al., 1999; Katz et al., 2002; Koutsoyiannis, 2004a; Papalexiou et al., 2013).

Based on the asymptotic results of the Extreme Value Theory (Coles, 2001), the AMS distribution of a random variable $X$ is well described by the Generalized Extreme Value (GEV) distribution family. If we represent the AMS by $(x_1, x_2, ..., x_n)$, the GEV cdf can be written as (Coles, 2001):

$$F(x) = \exp\left\{-\left[1 + \xi\left(\frac{x - \mu}{\sigma}\right)^{1/\xi}\right]\right\}$$  \hspace{1cm} (5)

where $\xi \neq 0$, $-\infty < x \leq \mu + \sigma/\xi$ if $\xi < 0$ (bounded tail), and $1/\mu + \sigma\xi < x < +\infty$ if $\xi > 0$ (heavy tail). $\mu \in \mathbb{R}$, $\sigma > 0$ and $\xi$ respectively represent the location, scale, and shape parameters of the distribution. The shape parameter describes the characteristics of the distribution tails and the frequency of the extremes generated by $F(x)^{R1}$. Thus, high order quantile estimation is particularly affected by the value of $\xi$. If $\xi = 0$ (light-tailed shape, Gumbel distribution), Eq. (5) reduces to:

$$F(x) = \exp\left\{-\exp\left\{-\frac{x - \mu}{\sigma}\right\}\right\}$$  \hspace{1cm} (6)

where $-\infty < x < +\infty$.

In applications, the GEV distribution is frequently constrained by the assumption that $\xi = 0$ (i.e., to the Gumbel distribution), due to the difficulty of estimating significant values of the shape parameter when the recorded series are short (e.g., Borga et al., 2005; Overeem et al., 2008; CSA, 2012). However, based on theoretical and empirical evidence, many authors have shown that this assumption is too restrictive for extreme precipitation, and may lead to important underestimations of the extreme quantiles (e.g., Koutsoyiannis, 2004a, b; Overeem et al., 2008; Papalexiou et al., 2013, Papalexiou and Koutsoyiannis, 2013). Instead, approaches aimed at increasing the sample size series length $^{R1}$ may be used to improve the estimation of the GEV distribution shape parameter (for instance, the Regional Frequency Analysis (RFA), Hosking and Wallis, 1997). Among these approaches, SS models constitute an appealing way to pool data from different samples (durations) and reduce uncertainties in GEV parameters.

For the GEV distribution it is straightforward to verify that, if $X \overset{d}{=} GEV(\mu, \sigma, \xi)$ then $\lambda X \overset{d}{=} GEV(\lambda \mu, \lambda \sigma, \xi)$ for any $\lambda \in \mathbb{R}$. This means that the GEV family described by Eq. (5) and (6) satisfies Eq. (2) and thus complies with scale invariance for any constant multiplicative transformation of $X$. Under this assumption the wide sense SS definition [Eq. (3)] gives:

$$\mu_d = d^{-H}\mu_s, \quad \sigma_d = d^{-H}\sigma_s, \quad \text{and} \quad \xi_d = \xi_s$$  \hspace{1cm} (7)

where $\mu_s$, $\sigma_s$, and $\xi_s$ represent the GEV parameters for a reference duration $d^*$ chosen, for simplicity, as $d^* = 1$, so that $\lambda = d$.

2.2 SS GEV estimation

Taking advantage of the scale invariant formulation of the GEV distribution, many authors have proposed simple scaling IDF and DDF models for extreme precipitation series (e.g., Yu et al., 2004; Borga et al., 2005; Bougadis and Adamowski, 2006;
In these cases, the scaling exponent and the GEV parameters are generally estimated in two separate steps: first, the $H$ value is empirically determined through a log-log linear regression, as described above; then, GEV parameters $\mu^*$, $\sigma^*$, and $\xi^*$ for the reference duration $d^*$ are estimated on the pooled sample of all available durations. Classical estimation procedures, such as GEV Maximum-Likelihood (ML) (Coles, 2001) or Probability Weighted Moment (PWM) (Greenwood et al., 1979; Hosking et al., 1985), can be used. In a few other cases, a Generalized Additive Model ML (GAM-ML) framework (Coles, 2001; Katz, 2013) has also been used to obtain the joint estimate of $H$, $\mu^*$, $\sigma^*$, and $\xi^*$ through the introduction of the duration as model covariate (e.g. Blanchet et al., 2016).

3 Data and study region

Four station datasets were used for the construction of intensity AMS at different durations: the Daily Maxima Precipitation Data (DMPD) and the Hourly Canadian Precipitation Data (HCPD) datasets provided by Environment and Climate Change Canada (ECCC) and the MDDELCC [in french Ministère du Développement Durable, de l’Environnement et de la Lutte contre les Changements Climatiques] for Canada, and the Hourly Precipitation Data (HPD) and 15-Min Precipitation Data (15PD) datasets made available by the National Oceanic and Atmospheric Administration (NOAA) agency [http://www.ncdc.noaa.gov/data-access/land-based-station-data] for United States. The total number of stations was approximately 3400, with roughly 2200 locations having both DMPD and HCPD series, or both HPD and 15PD series. The majority of stations are located in the United States and in the southern and most densely populated areas of Canada. In northern regions the station network is sparse and the record length does not generally exceed 15 or 20 years. Moreover, for most of DMPD and HCPD stations, the annual recording period does not cover the winter season and available series generally include precipitation measured from May to October. For this reason, the year was defined as the period from June to September for the stations located north of the 52nd Parallel [122 days a year were used], while the period from May to October was used for remaining stations [184 days a year].

Data were collected through a variety of instruments [e.g., standard, tipping-bucket, and Fischer-Porter rain gauges] and precipitation values were processed and checked using both automated and manual methods (CSA, 2012, HPD and 15PD online documentation). Most often, observations were recorded by tipping-bucket gauges with tip resolution from 0.1 mm to 2.54 mm (CSA, 2012; Devine and Mekis, 2008). 15 min series usually present the coarser instrument resolution, with a minimum non-zero value of 2.54 mm, observed for about 80.5% of 15PD stations. The effects of such a coarse instrument resolution on simple scaling estimates could be important leading to empirical $X_d$ cdfs becoming step-wise functions with a low number of steps. Some preliminary analyses aiming at evaluating these effects on SS estimates are presented in the supplementary material [see Fig. S2 and S3]. However, the 15PD dataset is important considering the associated network density and its fine temporal resolution, and thus it has been retained for our study. The main characteristics of the available datasets are summarized in Table 1.

The scaling AMS datasets were constructed according to the following steps:

(i) Three duration sets were defined: a) 15 min to 6 h with a 15min step; b) 1 h to 24 h with a 1h step; c) 6 h to 168 h (7
days) with a 6h step. These duration sets are hereinafter referred to as Short-Duration (SD), Intermediate-Duration (ID), and Long-Duration (LD) datasets, respectively.

(ii) Meteorological stations that were included in each final dataset were selected according to the following criteria: 1) precipitation series must have at least 85% of valid observations each year, otherwise the year was considered as missing; 2) each station must have at least 15 valid years; 3) for each station, it was possible to compute AMS for all durations considered in the scaling dataset (e.g., HCPD-HR² and HPD stations were not included in the SD dataset because only hourly durations were available). Note that, in order to exclude outliers possibly associated with recording or measurement errors, extremely large observations were discarded and assimilated to missing data. In particular, as in some previous studies (e.g., Papalexiou and Koutsoyiannis, 2013; Papalexiou et al., 2013), an iterative procedure was applied prior to step (ii)-1) to discard observations larger than 10 times the second largest value of the series.

(iii) A moving window was applied to 15PD, HCPD-HR², and HPD series to estimate aggregated series at each duration. For DMPDDMR² series, a quality check was also implemented in order to guarantee that precipitation intensities recorded each day at different durations were consistent with each other. For instance, each pair of DMPDDMR² intensity \( x_{d_1}, x_{d_2} \) observed at durations \( d_1 < d_2 \) must respect the conditions \( x_{d_2}/x_{d_1} \leq 1 \) and \( d_1 x_{d_1} \leq d_2 x_{d_2} \) derived from the definitions of daily maxima rainfall intensity and depth; otherwise all DMPD values recorded that day were discarded and assimilated to missing data. The condition \( d_1/d_2 \leq x_{d_2}/x_{d_1} \leq 1 \), otherwise the day was considered as missing.

(iv) For each selected station, annual maxima were extracted for each valid year and duration. For stations having both DMPD and HCPD series, or 15PD and HPD series, for each year, the annual maxima extracted from these two series were compared and the maximum value was retained as the annual maximum for that year. Then, for stations having both DM and H series, or 15PD and HPD series, over a common time period, annual maximum values between these two series were retained.

Major characteristics of each scaling AMS dataset are reported in Table 2.

4 SS estimation through Moment Scaling Analysis (MSA)

Moment Scaling Analysis (MSA) for the SD, ID, and LD datasets was carried out to empirically validate the use of SS models for intensity AMS. Assessing the validity of the SS hypothesis for various duration intervals also aimed at determining the presence of different scaling regimes for precipitation intensity distributions. The spatial distribution of the scaling exponents was then analyzed to assess the dependence of SS on local geoclimatic characteristics.

In order to identify possible changes in the SS properties of AMS distributions, various scaling intervals were defined for the MSA. In particular, all possible subsets with 6, 12, 18 and 24 contiguous durations were considered within each dataset. Figure 1 and Figure 2 show the 136 scaling intervals thereby defined: 40 scaling intervals for SD and IS, and 56 scaling intervals for LD. For instance, the first matrix on the left of Fig. 1(a) presents the 6-duration scaling intervals 15min - 1.5h, 30min - 1.75h, ..., 4.75h - 6h defined from the SD dataset [i.e. the 19 scaling intervals containing six contiguous durations defined with a 15min increment, with 15min step], while Fig. 1(d) shows an example of the first four 6-duration scaling
intervals for the ID dataset [i.e. 1h-6h, 2h-7h, 3h-8h, and 4h-9h, containing six contiguous durations defined with an increment of 1h]. This procedure was defined in order to evaluate the sensitivity of the SS estimates to changes in the first duration $d_1$ of the scaling interval and in the interval length [i.e. the number of durations included in the scaling interval] variability of the SS estimates when changing the position of the scaling interval [hereinafter identified by its first duration $d_1$; see examples in Figure 1(d)] and the number of durations considered.

For each scaling interval (for simplicity, their index has been omitted), the validity of the SS hypothesis was verified according to the following steps:

1. **MSA regression**: for $q = 0.2, 0.4, \ldots, 2.8, 3$, the slopes $K_q$ of the log-log linear relationships between the empirical $q$--moments $\langle X_d^q \rangle$ of $X_{d_1}, X_{d_2}, \ldots, X_{d_D}$ and the corresponding durations $d_1, d_2, \ldots, d_D$ in the scaling interval $[d_1, d_D]$ were estimated by Ordinary Least Squares (OLS). Order $q \geq 3$ were not considered because of the possible biases affecting empirical high order moment estimates.

2. **Slope test**: Regressing the MSA slopes $K_q$ on $q$, the hypothesis that the estimated $K_q$-exponents vary linearly with the order of moment $q$ was verified. To this end, a Student’s $t$-test was used to test the null hypothesis $H_0: \beta_1 = K_1$, where $\beta_1$ is the slope coefficient of the simple regression model $K_q = \beta_0 + \beta_1 q$. If $H_0$ was not rejected at the significance level $\alpha = 0.05$, the SS assumption for the scaling interval was considered appropriate for the scaling interval and the simple scaling exponent $H = K_1$ was retained.

3. **Goodness-of-Fit (GOF) test**: for each duration $d$, the goodness of fit of the $X_d$ distribution under SS was tested using the Anderson-Darling (AD) and the Kolmogorov-Smirnov (KS) tests. These tests aim at validating the appropriateness of the scale invariance property for approximating the $X_d$ cdf by the distribution of $X_{d,ss} = d^{-H} X_{d^*}$. To this end, the pooled sample

$$x_{d^*} = (x'_{d_1}, \ldots, x'_{d_j}, \ldots, x'_{d_D}) \quad (8)$$

of the $D$ rescaled AMS, $x'_{d_j}$, was used to define $X_{d^*}$ under the SS assumption, considering all the durations $d_j$, with $j = 1, \ldots, D$, in the scaling interval. Each rescaled sample $x'_{d_j}$ of the annual maxima $x_{d_j,i}$, $i = 1, \ldots, n$, observed for the duration $d_j$ was obtained by simply inverting Eq. (2) for $d^*$:

$$x'_{d_j} = \left( d_j^H x_{d_j,1}, d_j^H x_{d_j,2}, \ldots, d_j^H x_{d_j,i}, \ldots, d_j^H x_{d_j,n} \right) \quad (9)$$

where $n$ represents the number of observations (years) available for each duration. In this way, $n \times D$ rescaled observations were included in $x_{d^*}$.

As in previous applications (e.g., Panthou et al., 2014), the AD and KS tests were then applied at significance level $\alpha = 0.05$ to compare the empirical distributions (Cunnane plotting formula, Cunnane, 1973) of the SS sample, $x_{d,ss} = d^{-H} x_{d^*}$, and the non-SS sample, $x_d$.

For each duration $d$, the goodness of fit of the $X_d$ distribution under SS was tested using the Anderson-Darling (AD) and the Kolmogorov-Smirnov (KS) tests. These tests aim at validating the appropriateness of the scale invariance property for approximating the $X_d$ cdf by the distribution of $\lambda^{-H} X_{d^*}$. To this end, the pooled sample
\[ x_{d} = (x'_{d_1}, \ldots, x'_{d_j}, \ldots, x'_{d_D}) \]  

(8)

of the rescaled AMS, \( x'_{d_j} \), for all durations \( d_j, j = 1, \ldots, D \), in the scaling interval, was used to define \( X_d \) under the SS assumption. Using \( d^* = 1 \) h, the rescaled sample \( x'_{d_j} \) of the annual maxima \( x_{d_j,i}, i = 1, \ldots, n \), observed for \( d_j \) was:

\[ x'_{d_j} = \left( d_j^H x_{d_j,1}, d_j^H x_{d_j,2}, \ldots, d_j^H x_{d_j,i}, \ldots, d_j^H x_{d_j,n} \right) \]  

(9)

where \( n \) represents the number of observations (years) available for each duration. Hence, \( n \times D \) rescaled observations were included in \( x_{d^*} \).

The tests were then applied at significance level \( \alpha = 0.05 \) to compare \( x_d \) and \( x_{d^*} \) empirical distributions (Cunnane plotting formula, Cunnane, 1973) as in previous precipitation scaling applications (e.g., Panthou et al., 2014). In fact, despite the low power of KS and AD tests for small sample tests, they represent the only suitable solution to the problem of comparing empirical cdfs when the data do not follow a normal distribution. Because both AD and KS are affected by the presence of ties in the samples (e.g., repeated values due to rounding or instrument resolution), a permutation test approach (Good, 2013) was used to estimate test p-values. According to this approach, data in \( x_d \) and \( x_{d,ss} \) were pooled and randomly reassigned to two samples having same sizes as pooled data of \( x_d \) and \( x_{d^*} \) were randomly reassigned the SS and non-SS samples. Then, the test statistic distribution under the null hypothesis of equality of the \( X_{d,ss} \) and \( X_d \) distributions was approximated by computing its value over a large set of random samples. Finally, the test p-value was obtained as the proportion of random samples presenting a test statistic value larger than the value observed for the original sample.

The mean error resulting from approximating the \( X_d \) distribution by the SS model was then evaluated in a cross-validations setting. For this analysis, each duration was iteratively excluded from each scaling interval and the scaling model re-estimated at each station. Predictive ability indices, such as the Mean Absolute Error (MAE) and the Root Mean Squared Error (RMSE) between empirical and SS distribution quantiles, were estimated for highest quantiles. In particular, to focus on return periods of practical interest for IDF estimation, only quantiles larger than the median were considered (i.e., only return periods greater than 2 years).

The average over all stations of the normalized RMSE, \( \bar{\varepsilon}_{x_d} \), for each scaling interval and duration was used:

\[ \bar{\varepsilon}_{x_d} = \frac{1}{n_s} \sum_{s=1}^{n_s} \varepsilon_{x_{d,s}} \]  

(10)

\[ \bar{\varepsilon}_{x_d} = \frac{1}{n_s} \sum_{s=1}^{n_s} \varepsilon_{x_{d,s}} \]  

(10)R1

where \( n_s \) is the number of valid SS stations in the dataset.
and $\epsilon_{x_{d,s}} \frac{r_{x_{d,s}}}{R_1}$ and $\bar{x}_{d,s}$ are, respectively, the RMSE and the mean value of all $X_d$ quantiles of order $p > 0.5$ at station $s$. Note that the normalized RMSE is a measure of error, meaning that values of $\epsilon_{x_{d,s}}$ closer to 0 correspond a better fit than larger values. R1

4.1 Model estimation and validation

Figure 1 presents the results of points 1 to 3 of the procedure for the evaluation of the SS validity. It shows, for each scaling interval and duration, the proportion of valid SS stations [Fig. 1(a)-(c)]. As showed in the example in Fig. 1(e), for each scaling interval, valid SS stations were defined as stations having not rejected both the Slope test for the scaling interval and the GOF tests for each duration included in this scaling interval.

As expected, the proportion of valid SS stations decreased when the number of durations within the scaling interval increased and with decreasing $d_1$. This is particularly evident for short $d$ in SD and ID datasets. More GOF test rejections were observed for longer scaling intervals [not shown], due to the higher probability of observing large differences between $x_d$ and $x_{d,ss}$ quantiles when $x_{d,ss}$ had larger sample size $x_d$ was larger and included data from more distant durations. However, several factors can impact GOF test results when shorter $d_1$ are considered included in the scaling intervals. First, the SS hypothesis could be rejected due to the presence of very large values in short-duration samples, to which GOF tests are particularly sensitive. Second, when considering durations close to the temporal resolution of the recorded series [i.e., 15 min in SD and 1 h in ID and LD], stronger underestimations could affect the measure of precipitation because intense rainfall events are more likely to be split between two consecutive time steps. Finally, preliminary analyses [Fig. S2 and S3 in the supplementary material] showed that the largest GOF test rejections could also be connected to the coarse instrument resolution of 15PD series, which, similar to the temporal resolution effect, induces larger measurement errors in the shortest duration precipitation series.

Valid SS station proportions between 0.99 and 1 were always observed for GOF tests in ID and LD datasets, except for some durations shorter than 3 h (ID dataset) or 6 h (LD dataset). For all three datasets, no particular pattern was observed for slope test results [not shown], with at most 2% of the stations within each scaling interval displaying a non linear evolution of the scaling exponent with the moment order.

When considering both GOF and Slope test, with the exception of some durations $\leq 1$ hour, the proportion of stations satisfying SS was higher than 0.9, and the majority of scaling intervals [65%, 90%, and 98% of the scaling intervals in SD, ID, and LD, respectively] included at least 95% of valid SS stations. For each scaling interval, only valid SS stations were considered in the rest of the analysis.

Figure 2 presents, for each scaling interval and duration, the station average, $\bar{r}_{x_{d,s}} \frac{r_{x_{d,s}}}{R_1}$, of the normalized RMSE. These graphics show that mean relative errors on intensity quantiles did not generally exceed 5% of the precipitation estimates for 6-duration scaling intervals [Fig. 2, first col.]. Larger errors were observed for durations at the border of the scaling intervals. Not
surprisingly, this result underlines that, in a cross-validation setting, both the MSA estimation of $H$ and the $X_{d,ss}$ approximation are less sensitive to the exclusion of an inner duration of the scaling interval than to the exclusion of $d_1$ or $d_D$. Conversely, the extrapolation under SS of the $X_d$ distribution is generally less accurate if $d$ is outside the range of durations used to estimate $H$. Moreover, as for the valid SS station proportion, the performances of the model deteriorated with decreasing $d_1$ and with increasing scaling interval length, especially for durations at the border of the scaling intervals. However, for more that 70% of 12-, 18-, and 24-duration scaling intervals, $\bar{\tau}_{x_d} \bar{\tau}_{x_d} \geq 0.25$ were observed for 15 min in 12-duration or longer scaling intervals, pointing out the weaknesses of the model in approximating short duration extremes when the scaling interval included durations $\geq 3$ h.

4.2 Estimated scaling exponents and their variability

In order to evaluate the sensitivity of SS to the considered scaling interval, the variability of $H$ with $d_1$ has been analyzed. Then, the spatial distribution of the scaling exponents for each scaling interval was studied to assess the uncertainty in $H$ estimation and the dependence of SS exponents on local geoclimatic characteristics.

Investigating the variability of the scaling exponent with the scaling interval is particularly important since, if SS is assumed to be valid between some range of durations, one should expect that $H$ remains almost unchanged over the various scaling intervals included in this range. For this reason, the variation $\Delta H_{(j)}$ of the scaling exponents computed for overlapping scaling intervals having the same $d_1$ but different lengths was analyzed.

The median, Interquartile Range (IQR), and quantiles of order 0.1 and 0.9 of the $H$ distribution across stations, are presented in Fig. 3(i) for each 6-duration scaling interval. Figures 3(ii)–(iv) show the distribution of the scaling exponent variation $\Delta H_{(j)}$ observed over stations when each scaling interval is lengthened from 6 to 12, 18, and 24 durations.

For each station and each $d_1$, $\Delta H_{(j)}$ was defined as:

$$\Delta H_{(j)} = H_{(j)} - H_{(6)}$$

where $j = 12, 18, \text{ or } 24$ represent the number of durations considered in the specified scaling interval, $H_{(j)}$ is the corresponding scaling exponent, and $H_{(6)}$ is the scaling exponent estimated for the corresponding 6-duration scaling interval (i.e., the 6-duration interval having the same $d_1$). If SS is appropriate over a range of durations, $\Delta H_{(j)}$ is expected to be small for scaling intervals defined within this range.

The median, Interquartile Range (IQR), and quantiles of order 0.1 and 0.9 of the $H$ distribution across stations, are presented in Fig. 3(i) for each 6-duration scaling interval. Figures 3(ii)–(iv) show the distribution over valid SS stations of $\Delta H_{(j)}$ for all relevant scaling intervals. Figures 3(ii)–(iv) represent the changes observed in $H$ values when the scaling interval length and $d_1$ increased. Median $\Delta H_{(j)}$, as well as its (IQR)–(IR), increased with the number of durations added to the scaling interval for all $d_1$. For the 24-duration scaling interval "1h - 24h" (ID dataset), for instance, median $\Delta H_{(24)} = 0.047$ was observed. For the interval "15min - 6h" (SD dataset), $\Delta H_{(24)}$ was even larger, with a median scaling exponent variation approximately equal to 0.087 and with 25% of stations having $\Delta H_{(24)} \geq 0.11$. These results indicate that, for some stations, a dramatic difference could exist in IDF estimations obtained with the different definitions of the scaling interval. Changes in $H$ values were also
important when comparing 6- and 12-duration scaling intervals when \( d_1 \leq 1 \) h (SD and ID datasets) and in LD dataset [Fig. 3 (ii)]. Nonetheless the median scaling exponent variation was generally smaller than 0.05, except for a relatively small proportion of stations. Equally important, \(|\Delta H_{(j)}|\) was generally centered on 0 and for all \( d_1 \geq 1 \) h more than 50% of stations had \(|\Delta H_{(12)}|\) \leq 0.025 (SD dataset) and \(|\Delta H_{(18)}|\) \leq 0.03 (ID dataset) [Fig. 3 (ii)-(iii)].

The smallest median \( H \) values were observed for the shortest \( d_1 \) (\( d_1 \leq 30 \) min) in Fig. 3 (a-i), and for the longest \( d_1 \) s in Fig. 3 (c-i). Scaling intervals beginning at 15 and 30 min also displayed the smallest variability across stations. Although fewer stations were available for these intervals (only 15PD stations were used and the number of valid SS stations was smaller), this result is consistent with previous reports in the literature demonstrating that \( H \) values are spatially more homogeneous for short durations.

A larger dispersion of \( H \) values was observed when \( d_1 \) ranged between approximately 1 and 5 h, in particular in the SD dataset, for which the 10th-90th percentile difference almost covered the entire range of observed \( H \) values [Fig. 3 (i)]. This result could be in part explained by the fact that, if the scaling interval length is fixed, then the variance \( V[\ln(d)] \) of the MSA regression covariate decreases as \( d_1 \) increases. In fact, the use of a logarithmic scale for the MSA regression implies that the mean distance between durations in the scaling interval decreases as \( d_1 \) increases. Thus, regression errors of the same magnitude in short and long \( d_1 \) scaling intervals differently affect the OLS variance of \( H \), especially when scaling intervals are short. This may result in larger uncertainty of \( H \) for longer \( d_1 \) scaling intervals of SD. Moreover, as showed in next sections, \( H \) variability across stations may be effectively larger due to the greater spatial variability of the scaling exponent for \( d_1 \) longer than a few hours.

Largest median \( H \) were observed for \( d_1 \) greater than 10 hours [Fig. 3 (b-i)] and lower than 2 days [Fig. 3 (c-i)], with approximately half of the stations having \( H \geq 0.8 \). This means that a stronger scaling (i.e., larger \( H \) values) is needed to relate extreme precipitation distributions at approximately 12-hours to distributions at daily and longer scales. It may therefore be expected that the stations characterized by \( H \) closer to 1 are located in geographical areas where differences in precipitation distributions are important among temporal scales included in these scaling intervals.

Examples of the spatial distributions of the scaling exponent are given in Fig. 4 and 5 for the first and last \( d_1 \) for each interval length and dataset, respectively. Since only one 24-duration scaling interval was defined for both the SD and ID datasets, only scaling intervals containing 6, 12, and 24 (Fig. 4) or 18 (Fig. 5) durations are presented. This avoids the redundancy of showing twice the "15min - 6h" (SD dataset) and "1h - 24h" (ID dataset) scaling intervals.

Generally, the scaling exponent displayed a strong spatial coherence and varied smoothly in space, although a more scattered distribution of \( H \) characterizes maps in Fig. 5. In this last figure, the local variability of \( H \) may be attributed to the larger estimation uncertainties, as previously mentioned. Meaningful spatial variability and clear spatial patterns emerged for \( d_1 \geq 1 \) h. In fact, for stations located in the interior and southern areas of the continent, a shift from weaker scaling regimes (smaller \( H \)) to higher \( H \) values was observed as \( d_1 \) increases [e.g., second and third rows of Fig. 4]. On the contrary, a smoother evolution of \( H \) over the scaling intervals characterized the northern coastal areas, especially in north-western regions, and the Rockies, where \( H > 0.75 \) values were rarely observed even for greater \( d_1 \) values.
5 Regional analysis

Regional differences in scaling exponents were investigated. Only the results for the 6-duration scaling intervals are presented, similar results having been obtained for longer scaling intervals [see the supplementary material, Fig. S5 and S6 for 12- and 18-duration scaling intervals]. Stations were pooled into six climatic regions based on a previous classification suggested by Bukovsky (2012) [see Fig. 6]. Stations outside the domain covered by the Bukovsky regions were attributed to the nearest region. Regions with less than 10 stations were not considered (regions without colored borders in Fig. 6) and region A1 (W_Tun) was kept separated from region A2 (NW_Pac) because only 14 stations were available in region A1 (W_Tun) for ID and LD datasets.

To provide deeper insights about regional features of precipitation associated with specific scaling regimes two variables related to the precipitation events observed within AMS were also analyzed: the mean number of events per year, $\bar{N}_{eve}$, and the mean wet time per event, $\bar{T}_{wet}$, contributing to AMS within each scaling interval. For a given year and station, annual maxima associated to different durations of a given scaling interval were considered to belong to the same precipitation event if the time intervals over which they occurred overlapped. [see Fig. 7 (g); in this example 3, 4, and 5 h annual maxima are associated with the first event while 1, 2, and 6 h annual maxima are associated to the second event]. The mean number of events at each station was then computed:

$$\bar{N}_{eve} = \frac{1}{n} \sum_{i}^{n} N_{eve,i}$$  \hspace{1cm} (13)

with $N_{eve,i}$ the number of non-overlapping time intervals, i.e. the number of different events contributing to AMS during the $i^{th}$ year of record. The distribution of $\bar{N}_{eve}$ values within each region is presented in Fig. 7.

The mean wet time per event contributing to AMS, $\bar{T}_{wet}$, was defined as the mean number of hours with non-zero precipitation within each event. Details on the calculation of $\bar{N}_{eve}$, $\bar{T}_{wet}$, and the corresponding results are presented in the supplementary material [Sect. S2 and Fig. S4 - S5R1].

5.1 Regional variation of the scaling exponents.

Figure 7 shows the distribution of $H$ within each region. Three types of curves can be identified. First, curves in Fig. 7 (a) to (c) have a characteristic smooth S shape. Conversely, Fig. 7 (d) displays a rapid increase of $H$ for scaling intervals defined in ID and LD datasets until $d_1 = 2$ days, preceded and followed by two plateaus, one for the longest $d_1$ with remarkably high $H$ values, and one for the shortest $d_1$ with small $H$ values. Finally, an inverse-U-shaped curve can be seen in Fig. 7 (e) and (f), with globally high $H$ values already reached at sub-daily durations in dry regions (E).

The difference between Fig. 7 (a) and (e)-(f) can be partially explained by the weaker impact of convection processes in generating very short duration extremes in regions A1 and A2 with respect to southern areas (regions E and F). For northern regions, the transition between short and long duration precipitation regimes may be smoothed by cold temperatures which moderate short-duration convective activity, especially for W_Tun (region A1). The topography characterizing the northern
pacific coast may explain the smoothing effect for the curve of region \textit{NW\_Pac} (A2): precipitation rates at daily and longer scales are enhanced by the orographic effect acting on synoptic weather systems coming from the Pacific Ocean (Wallis et al., 2007).

Similarly, mountainous regions in C [Fig. 7 (c)] displayed the smallest variations of $H$ over $d_1$, indicating that analogous scaling regimes characterize both short- and long-duration scaling intervals. Again, this may be related to the important orographic effects of precipitation in these regions that are involved in the generation of extremes for both sub-daily and multi-daily time scales. The mean number of events per year in regions A and C was higher than in regions E-F, in particular for SD scaling intervals, and displayed steeper decreases with increasing $d_1$ [Fig. S4\_R1 (a) and (c) in the supplementary material\textsuperscript{R1}].

Main differences between regions B and A were the stronger scaling regimes observed in B, which were mainly due to contributions from stations located in the south-eastern part of the \textit{E\_Bor} region (not shown). For scaling intervals in the ID dataset, region B was also characterized by the highest mean number of events per year, with most of the stations presenting $\bar{N}_{eve} > 2$ for $d_1 = 1$ h and $d_1 = 2$ h and sharp decreases of $\bar{N}_{eve}$ with increasing $d_1$ [Fig. S4\_R1 (b) in the supplementary material\textsuperscript{R1}]. Moreover, a remarkably large range of $\bar{N}_{eve}$ was observed for $1$ h $\leq d_1 \leq 6$ h, suggesting that B may be highly heterogeneous. Two distinct scaling regimes can be observed for \textit{SW\_Pac} (region D) at, respectively, $d_1 \leq 3$ h (SD dataset) and $d_1 \geq 2$ days (ID dataset) [region D in Fig. 7 (d)]. These plateaus may be interpreted by recalling that $H = 1 - \frac{H_{depth} \cdot H_{intensity}}{1 - H_{depth}^2}$.

On the one hand, the low and constant $H$ observed for $d_1 \leq 3$ h indicates that the average precipitation depth increases with duration at the same growth rate for all these intervals. On the other hand, $H$ approximately equal to 0.9 at daily and longer durations demonstrates that the average precipitation depth associated with long-duration annual maxima remained roughly unchanged when the duration increased from 1.5 to 7 days ($\lambda_{H_{depth}} \approx 1$ in Eq. (3)). This, along with the fact that the scaling exponent increased almost monotonically for $1$ h $\leq d_1 \leq 24$ h (ID and LD datasets), suggests that extremes at durations shorter than $\sim 3$ h (SD dataset) drive annual maxima precipitation rates at longer scales, with the rapid and continuous decay in mean intensity caused by the increasing size of the temporal scale of observation.

For \textit{SW\_Pac} (region D), the relative absence of long-lasting weather systems able to produce important extremes for long durations, was confirmed by the analysis of $\bar{N}_{eve}$ and $\bar{T}_{wet}$ [see Fig. S4 and S5 of the supplementary material\textsuperscript{R1} for results on $\bar{T}_{wet}$ see Fig. S4 of the supplementary material\textsuperscript{R1}]. In fact, the mean number of events per year was relatively high for short durations (the median $\bar{N}_{eve}$ is equal to 1.82 for $d_1 = 15$ min and to 1.4 for $d_1 = 1$ h), while it rapidly decreased below 1.1 events per year for $d_1 \geq 6$ h (ID dataset) and for $d_1 \geq 18$ h (LD dataset). With the exception of $d_1 = 6$ h (LD dataset), at least 90% of \textit{SW\_Pac} stations had $\bar{N}_{eve} \leq 1.25$ for all $d_1 > 3$ h. In other regions, median $\bar{N}_{eve}$ were never smaller than 1.1 for the SD and ID datasets, except for $d_1 \geq 12$ h in region E.

These results suggests that both the distinctive topography of the west coast and the characteristic large-scale circulation of the south-west areas of the continent are crucial factors determining the transition between the two scaling regimes in region D\textsuperscript{R1}.

Median $H$ values displayed inverse-U shapes for the remaining regions with very small (IQR)-($H$)\textsuperscript{R1}, despite the high number of valid SS stations: a slow transition from lower to higher $H$ is observed approximately between 1 h and 12 h (region E) or 30 h (region F). The strongest scaling regimes were observed for $1$ h $\leq d_1 \leq 2$ days in arid western regions [Fig. 7 (e)], while
median $H$ values greater than 0.8 were only observed for approximately $6 \leq d_1 \leq 2$ days in more humid areas [7 (f)]. In both region E and F, very short-duration extremes are typically driven by convective processes, while a transition to different precipitation regimes may be expected between 1 h and a few hours. However, the smoother increase of $H$ visible in Fig. 7 (f) with respect to (e) may also indicate that, in eastern areas, the occurrence of sub-daily duration extremes are more likely associated to embedded convective and stratiform systems, or to mesoscale convective systems less active in western dry areas (Kunkel et al., 2012). On the contrary, for south-western dry regions [Fig. 7 (e)], where less intense summer extremes are expected compared to eastern areas [see supplementary material, Fig. S1], differences between short- and long-duration extreme precipitation intensity seem stronger since $H$ tended to scatter in a range of higher values: precipitation intensity moments strongly decrease as the duration increases for approximately $1 \leq d_1 \leq 12$ h.

In summary, these results suggest a regional effect on precipitation scaling of both local geographical characteristics, such as topography or coastal effects, and general circulation patterns. In general, the weakest scaling regimes were observed for short $d_1$ and along the west coast of the continent and seem to be connected to scaling intervals and climatic areas characterized by homogeneous weather processes. Low $H$ values correspond in fact to small variations in AMS distribution moments. On the contrary, stronger scaling regimes, which indicate important changes occurring in AMS moments across duration and, thus, in extreme precipitation features, were observed for longer $d_1$ in the other regions of the study area. According to these results, it would be important to take into account the climatological information included in the scaling exponent to improve SS and IDF estimation. Even more important, these results could help for the definition of IDF relationships at non-sampled locations by the construction of spatial models for the IDF parameter $H$.

### 6 SS GEV estimation

Results presented in this section are limited to a descriptive analysis of GEV parameter estimates, and to an assessment of the potential improvements carried out by SS GEV models with respect to PWM estimates of non-SS GEV models, for 6-duration scaling intervals. Similar results were generally obtained 12-, 18-, and 24-duration intervals [see supplementary material, Fig. S9 to S15].

In our study, the PWM procedure was applied to estimate SS-GEV parameters $\mu^*, \sigma^*$, and $\xi^*$ [Eq. (7)] from $x_{d^*}$ [Eq. (8)]. For each duration $d$, PWM were also used to estimate non-SS parameters $\mu_d, \sigma_d$, and $\xi_d$ from each of the non-SS samples $x_d$. In our application, GEV parameters $\mu^*, \sigma^*$, and $\xi^*$ [Eq. (7)] were estimated for $x_{d^*}$ [Eq. (8)] using the PWM procedure.

Preliminary comparisons of several estimation methods [e.g., PWM, classical ML estimators, and GAM-ML; see Sect. 2.2 Generalized Additive Model ML—see Coles (2001), Katz (2013)—in which the joint estimation of $H, \mu^*, \sigma^*$, and $\xi^*$ is obtained by the introduction of the duration as model covariate], showed that PWM slightly outperformed the other methods.

Quantiles estimated from the SS and the non-SS GEV were compared with empirical quantiles. Global performance measures, such as RMSE, were computed to evaluate the overall fit of the estimated GEV to the empirical $X_d$ distributions. In particular, mean errors between SS and non-SS quantile estimates and empirical quantiles were compared using the relative total RMSE.
ratio, $R_{rms}$, defined as:

$$R_{rms} = \frac{[\bar{R}_{ss} - \bar{R}_{non-ss}]}{\bar{R}_{non-ss}}$$

(13)

where

$$\bar{R}_{mod} = \sum_{d=d_1}^{D} \frac{\epsilon_{d,mod}}{\bar{x}_d}$$

(14)

represents the normalized mean square difference between model and empirical quantiles of order $p > 0.5$ for all the durations included in the scaling interval.

### 6.1 Estimated SS GEV parameters

Figure 8 presents the distributions over valid SS stations of the SS GEV parameters $\mu^*$ and $\sigma^*$ scaled at $d^* = 1$ h [Fig. 8 (a) and (b)] and $d^* = 24$ h [Fig. 8 (c)]. For the SD dataset, even for scaling intervals which did not include the reference duration $d^*$, the $\mu^*$ and $\sigma^*$ distributions appeared to be similar to the non-SS $\mu_d$ and $\sigma_d$ distributions [Figure 8, first row]. Conversely, in the ID and LD datasets, both $\mu^*$ and $\sigma^*$ distributions were more positively skewed than the corresponding non-SS distributions. Moreover, the relative differences $\Delta\mu = (\mu^* - \mu_d)/\mu_d$ and $\Delta\sigma = (\sigma^* - \sigma_d)/\sigma_d$ were estimated for each station, duration, and scaling interval. Two important results came out of this analysis [see Figures S10 and S11 of the supplementary material]. On the one hand, median values of $\Delta\mu$ and $\Delta\sigma$ were generally smaller than $\pm 5\%$ and $\pm 10\%$, respectively. On the other hand, $\Delta\sigma$ showed large positive values when $\xi_d = 0$ (i.e. Gumbel distributions), while small $\Delta\sigma < 0$ were estimated when $\xi_d \neq 0$ [not shown for conciseness]. These results are interesting since, while non-SS $\mu_d$ values are generally considered to be accurate estimates of the $X_d$ location parameter, small uncertainties are expected for the scale parameter only when the $\xi_d$ value is correctly assessed. In fact, the scale parameter $\sigma_d$ may be strongly biased when the shape parameter is spuriously set to zero ($\xi_d = 0$).

In addition, $\mu^*$ and $\sigma^*$ displayed strong coherence in their spatial distributions, which were characterized by an obvious North-West to South-East gradient [Fig. 9 shows examples for the scaling intervals 15min - 1.5h, 1h - 6h, and 6h - 36h]. Notable differences between SS GEV and non-SS estimates were observed for the shape parameter [third column of Fig. 8]. Firstly, SS $\xi^*$ were closer to 0 than non-SS $\xi_d$, for both positive and negative shape values. Secondly, $\xi^*$ distributions were generally more peaked around their median value than non-SS estimates.

Note that, the majority of stations had non-SS shape parameters $\xi_d$ non-significantly different from zero according to asymptotic test proposed by Hosking et al. [1985] for PWM GEV estimators applied at level 0.05. In particular, for each duration, non-SS models estimated light-tailed distributions (i.e., $\xi_d = 0$) for more than 85% of the stations, except that for $d = 15$ min and $d = 30$ min [Fig. 10, first col.]. Conversely, for all scaling intervals with $d_1 > 15$ min, SS GEV shape parameters were significantly different from zero for 40% to 45% of valid SS stations [Fig. 10, second col.]. Moreover, when using scaling
intervals of 12 durations or more, the proportion of $\xi^* > 0$ was always important (greater than 35%) for all 18- and 24-duration scaling intervals [see the supplementary material, Fig. S9]. The previous results suggest that pooling data from several durations may effectively reduce the sampling effects impacting the estimation of $\xi$, allowing more evidence of non-zero shape parameters, and, in many cases, of heavy tailed ($\xi > 0$) AMS distributions. This conclusion is consistent with previous reports, namely that 100- to 150-year series are necessary to unambiguously assess the heavy-tailed character of precipitation distributions (e.g., Koutsoyiannis, 2004b; Ceresetti et al., 2010). In general, typical values of $\xi \approx 0.15$, close to the estimated $\xi^*$ for cases in which $\xi^* > 0$, have also been reported (e.g., Koutsoyiannis, 2004b).

However, uncertainties on $\xi^*$ estimates remain important. Support for this comes from the spatial distribution of $\xi^*$, which was still highly heterogeneous, with local variability dominating at small scales [e.g., Fig. 9, third col.].

6.2 Improvement with respect to Non-SS models

The proportion of series for which the SS model RMSE, $r_{d,ss}$, was smaller than the non-SS GEV RMSE, $r_{d,non-ss}$, was analyzed [see the supplementary material, Fig. S12]. For cases with non-zero $\xi^*$, the fraction of stations with $r_{d,ss} < r_{d,nonss}$ was higher than 60% for most of the scaling intervals and durations. On the contrary, $r_{d,ss} > r_{d,nonss}$ was observed for the majority of stations (generally more than 70%) with $\xi^* = 0$.

Figure 11 presents the $R_{\text{rmse}}$ distribution over valid SS stations. When the SS distribution shape parameters were not significantly different from zero [Fig. 11, second col.], the relative increases in total RMSE were usually smaller than 0.1 in SD dataset, with only scaling intervals with $d_1 < 1$ h having greater $R_{\text{rmse}}$. For the ID and LD datasets, the medians of the total relative RMSE ratio distributions were smaller than 0.05 for $d_1 \geq 4$ h and $d_1 \geq 24$ h, respectively. Furthermore, more than 90% of stations had $R_{\text{rmse}} < 0.125$ for $d_1 \geq 6$ h (ID dataset) and $d_1 \geq 30$ h (LD dataset). When $\xi^* \neq 0$, an increase of the mean error in high order quantile estimates was observed for $d_1 = 15$ min (SD dataset) and $d_1 = 1$ h (ID dataset) for at least half of the stations [Fig. 11, first col.; note the different scale on the y-axis]. However, for all other $d_1$, negative $R_{\text{rmse}}$ values were observed for the majority of stations for all scaling intervals, with a median reduction up to 30% of the mean error. Note that also for 12- and 18-duration scaling intervals the median $R_{\text{rmse}}$ where generally negative for $d_1 > 1$ h and $\xi^* \neq 0$ [Fig. S13 and S14 of the supplementary material]. Conversely, $R_{\text{rmse}}$ increased for the majority of stations in all 24-duration scaling intervals having $d_1 < 12$ h [Fig. S15 of the supplementary material]. Note also that no particular spatial pattern characterized the $R_{\text{rmse}}$ estimates.

7 Discussion and conclusion

This study investigated simple scaling properties of extreme precipitation intensity across Canada and the United States. The ability of SS models to reproduce extreme precipitation intensity distributions over a wide range of sub-daily to weekly durations was evaluated. The final objective was to identify duration intervals and geographical areas for which the SS model can be used for the production of IDF curves.
The validity of SS models was empirically confirmed for the majority of the scaling intervals. In particular, the hypothesis of a scale-invariant shape of the $X_d$ distribution held for all duration intervals spanning from 1 h to 7 days based on the comparison of SS distributions to empirical quantiles. Less convincing results were obtained for durations shorter than 1 h, especially for the longest scaling intervals (24-duration intervals). One possible explanation is that the coarse instrument resolution of the available 15 min series may strongly impact both the validation tools (for instance, GOF tests) and SS estimates. These results provide important operative indications concerning the inner and outer cut-off durations for AMS scaling and show the importance of a deeper analysis to evaluate the impact of dataset characteristics (e.g., their temporal and measurement resolutions, or the series length) on the scale invariant properties of extreme precipitation.

The majority of the estimated scaling exponents ranged between 0.35 and 0.95, showing a smooth evolution over the scaling intervals and a well-defined spatial structure. Six geographical regions, initially defined according to a climatological classification of North America into 20 regions, displayed different features in terms of scaling exponent values. Specifically, distinct median values of $H$ were observed for the various geographical regions, each characterized by a different precipitation regime. This is consistent with results reported in the literature for some specific regions and smaller observational datasets (e.g., Borga et al., 2005; Nhat et al., 2007; Ceresetti et al., 2010; Panthou et al., 2014, and references therein). Moreover, while small and smooth changes of $H$ over the scaling intervals were observed in regions containing the majority of stations, one region, SW_Pac, displayed two dramatically distinct scaling regimes separated by a steep transition occurring between a few hours and 24 h. These results limit the applicability of SS models in SW_Pac, and were connected to the local features of intense precipitation events by the analysis of the mean number of events per year and the mean wet time of these events.

Weak scaling regimes, characterized by relatively small $H$ values ($H$ close to 0.5), were generally observed for scaling intervals containing very short durations (e.g., less than 2 h) and for regions on the west coast of the continent [regions A1, A2, and D; see Fig. 7]. For these scaling intervals and regions, we can expect that extreme precipitation events observed at various durations will have similar statistical characteristics, being governed by homogeneous weather processes.

The interpretation of high $H$ values (e.g., $H > 0.8$), observed between 1 and several days, depending on the region, is more complex. These scaling regimes correspond to mean precipitation depth that varies little with duration. This suggests an important change in precipitation regimes occurring at some durations included in the scaling interval. One interesting example was region SW_Pac (region D) for scaling intervals of durations longer than 1 day. In this case, the analysis of the mean number of events per year sampled in AMS suggested that very few long-duration extreme events were produced by large-scale dynamic precipitation systems.

For scaling intervals of durations longer than 4 days, scaling exponents seemed to converge to approximately 0.7 for all regions, except west coast regions (regions A1, A2, and D).

These results suggest that SS represents a reasonable working hypothesis for the development of more accurate IDF curves. Besides, the spatial distribution of the scaling exponent and its dependency on climatology should be taken into account when defining SS duration intervals since the accuracy of the SS approximation may depend on the range of considered temporal scales. Equally critical, estimated $H$ values were found to gradually evolve with the considered scaling intervals. In this respect, interesting extensions of the analysis should consider methods for the quantification of the uncertainty in $H$ estimations as well.
as the possibility of modeling the scaling exponent as a function of both the observational duration and the AMS distribution quantile/moment order, i.e. by the use of a multiscaling (MS) framework for IDF. Equally important, the events sampled by the AMS also showed different statistical features within different geographical regions and some specific results [e.g., for the SW_Pac region] stimulate the interest for an analysis of the scaling property of extreme precipitation by the use of a temporal stochastic scaling approach.

The evaluation of SS model performances under the assumption of GEV distributions for AMS intensity was then performed. Results indicate that the proposed SS GEV models may lead to a more reliable statistical inference of extreme precipitation intensity than that based on the conventional non-SS approach. In particular, a better assessment of the GEV shape parameter seems possible when pooling data from several durations under the scaling hypothesis. The use of the SS approximation may introduce biases in high quantile estimates when AMS distributions move drastically away from perfect scale invariance (short durations and/or longest scaling intervals). Nonetheless, decreases in the SS GEV RMSE with respect to non-SS GEV models for $d_1$ longer than a few hours and/or scaling intervals shorter than 24 durations indicate that quantile errors in IDF estimates can be generally reduced.

Caution is advised when interpreting these results due to the fact that high order empirical quantiles were used as reference estimates of true $X_d$ quantiles, which could be a misleading assumption especially when available AMS are short. Considering this limitation and our general results, any future extension of this study should investigate the possibility of introducing spatial information in scaling models as well as improvements of scaling GEV estimation procedures.

8 Data availability

The 15min Precipitation Data (15PD) and Hourly Precipitation Data (HPD) were freely obtained from NOAA/Climate Prediction Center (CPC) [http://www.ncdc.noaa.gov/data-access/land-based-station-data]. Hourly Canadian Precipitation Data (HCPD) and Daily Maxima Precipitation Data (DMPD) for Canada were acquired from Environment and Climate Change Canada (ECCC) and from the MDDELCC of Québec [data available upon request by contacting InfoClimat@mddelcc.gouv.qc.ca].
