9 **Abstract.** A long-term forecasting ensemble methodology, applied to water inflows into the Cheboksary reservoir (Russia),
10 is presented. The methodology is based on a combination of semi-distributed hydrological model ECOMAG that allows for
11 calculation of an ensemble of inflow hydrographs using two different sets of weather ensembles for the lead-time period: the
12 observed weather data is constructed on the basis of the Ensemble Streamflow Prediction methodology (ESP-based forecast),
13 and the synthetic weather data simulated by a multi-site weather generator (WG-based forecast). We have studied: (1)
14 whether there is any advantage of the developed ensemble forecasts in comparison with the currently issued operational
15 forecasts of water inflow into the Cheboksary reservoir, and (2) whether there is any noticeable improvement in a
16 probabilistic forecasts when using the WG-simulated ensemble compared to the ESP-based ensemble. We have found that
17 for 35-year period beginning from the reservoir filling in 1982, both continuous and binary model-based ensemble forecasts
18 (issued in deterministic form) overperform the actually used operational forecasts of the April-June inflow volume and,
19 additionally, provide acceptable forecasts of additional water regime characteristics, besides the inflow volume. We have
20 also demonstrated that the model performance measures (in verification period) obtained from the WG-based probabilistic
21 forecasts, which are based on a large number of possible weather scenarios, appeared to be more statistically reliable than the
22 corresponding measures calculated from the EPS-based forecasts based on the observed weather scenarios.

23 1 Introduction

24 Spring freshet is a hydrological phenomenon, which magnitude is highly dependent on the amount of water accumulated on
25 surface and in subsurface storages of the river basin during several months prior to the snowmelt. This dependency serves as
26 a physical basis to predictability of spring runoff (Li et al., 2009). As stated by Lettenmaier and Waddle (1978, p.1)
27 “snowmelt runoff is one of the few natural phenomena for which relatively accurate long-term forecast can be made”.

28 Implementation of this opportunity is crucial for the water reservoirs of the Volga-Kama Reservoir Cascade (VKRC) in
29 Russia – one of the world’s largest multi-purpose water management systems. The VKRC is located within the largest

1 European Volga River basin (area of 1 350 000 km²) and consists of 11 reservoirs that hold from 1 to 58 km³ of water and
2 conduct seasonal and multiyear flow regulation. The VKRC was designed to redistribute the highly uneven runoff of the
3 Volga River, with 2/3 of the annual runoff volume occurring during the two to four months of the spring-summer freshet.
4 This task, aimed at optimizing reservoir management for power production, navigation and flood protection, is even more
5 complex due to the requirement of annual spring water release to Lower Volga aimed at allowing for sturgeon spawning.
6 Such several-weeks-long regulated release with predefined amount and temperature of water during the spring freshet is a an
7 extremely complex task for water management (Avakyan, 1998). Hence, a reliable and forehand forecast of snowmelt inflow
8 into the VKRC reservoirs is crucial for the decision makers.

9 By the mid-1960s, the specific methods were developed, which underlie the contemporary operational forecast for VKRC
10 management (water supply forecast). For different reservoirs, the produced forecasts are based on two primary techniques:
11 the index methods, and the so-called physical-statistical methods (Gelfan and Motovilov, 2009; Borsch and Simonov, 2016).
12 Both methods produce deterministic (despite the term “physical-statistical”), purely data-driven forecasts and relate the
13 predictors (such as initial snow water equivalent, soil freezing and soil moisture indices, precipitation amount for the forecast
14 period) to the main predictand - the spring inflow into a reservoir. The initial basin characteristics are derived from
15 observations, yet the precipitation amount is typically set to the climatic mean. The operational water supply forecasts
16 methodology is used in real practice by water managers and remains unchanged over the past half-century.

17 While the utility of data-driven flow forecasts (which currently may be based on advanced statistical and machine learning
18 techniques) has been demonstrated on various examples (see, e.g. Abrahart et al., 2012), their skill and reliability depend on
19 the amount and stationarity of available data and are not always adequate. It would be difficult to expect a forecast
20 improvement within the existing framework of the purely data-driven approach because of reduction of the observational
21 network in the Volga basin (estimated at 30% in (Borsch and Simonov, 2016)), non-homogeneity of the observations caused
22 by changes in the measurement techniques, changes in climate, land use and so on.

23 An opportunity to improve the operational water supply forecasts of water inflow into VKRC lies in shifting from the
24 traditional exclusively data-driven forecasts towards hydrological model-based forecasts, and from deterministic
25 methodology to the one using ensembles with a possibility to characterise forecast uncertainty. During the last 20-30 years
26 there have been a general understanding of the necessity of such a shift to ensemble streamflow prediction (ESP) systems
27 (e.g., Day, 1985), and a considerable research effort in this direction (Franz et al., 2003; Wood and Lettenmaier, 2006; Li et
28 al., 2009; Shukla and Lettenmaier, 2011; Yossef et al., 2013; Najafi and Moradkhani 2015; Demirel et al. 2015; Beckers et
29 al. 2016; Arnal et al., 2017; Mendoza et al. 2017). Such systems are currently used more and more in operational mode by
30 national weather services in the Untied States (e.g. McEnery et al., 2005), Canada (Druce, 2001) and other countries
31 (Pappenberger et al., 2016).

1 In its original form, an ESP is based on an assumption that historical time series of the observed meteorological variables are
2 representative for a local climate. These series are used as an ensemble of meteorological inputs into a hydrological model to
3 simulate corresponding ensembles of streamflow forecasts. This allows for considering uncertainty in weather conditions
4 during the forecast horizon and provide an opportunity to quantify the corresponding uncertainty (and hence, risk) in the
5 forecast-based decision support systems for reservoir management. In addition, utilizing the process-based (physically-
6 based) hydrological models results in increasing the physical adequacy of forecasts and, potentially, in improving forecast
7 accuracy in comparison with the methods currently used in operational practice. However, such quantitative comparisons is
8 not a common place; to our knowledge the only example is the comprehensive experiment presented by Mendoza et al.
9 (2017) and comparing the ESP model-based forecasts with the operational data-driven forecasts for a multi-year historical
10 period.

11 The observed weather scenarios that are used within the ESP framework do not encompass all of the possible weather
12 conditions for the forecast period. It is desirable to account not only for the observed weather, but for possible weather
13 conditions that might lead to freshet events of rare occurrence. Assessing the magnitude of such an event might be crucial for
14 decision making. Moreover, since the ensemble size is limited to the number of the historical years, one may need to deal
15 with the statistical problems stemming from large sample errors. For instance, Buizza and Palmer (1998) demonstrate
16 improvement of the weather forecast skill as the ensemble size increases, wherein degree of improvement depends on the
17 verification measure used. Particularly, the ranked probability skill score is strongly dependent on ensemble size and
18 negatively biased (see also Müller et al. 2005, Weigel et al., 2007). Different aspects of the ensemble size effect on statistical
19 properties of the ensemble weather forecast and verification scores are studied by Richardson (2001), Ferro et al. (2008),
20 Najafi et al. (2012). A solution can be seen in employing the synthetic, stochastically generated time series of weather
21 variables instead of the historical data used within the ESP framework. As a result, hydrological system response to a large
22 variety of possible weather conditions can be reproduced, and a sizeable ensemble of forecasts can be generated.

23 To the best of the authors' knowledge, there are not too many examples of employing stochastic weather generators (WG)
24 within the framework of long-term ensemble forecasting. Hanes et al. (1977) were probably the first who used Monte-Carlo
25 simulated sequences of daily precipitation to drive the conceptual US Geological Survey hydrological model and provide
26 ensemble seasonal forecast of snowmelt runoff volume. Kuchment and Gelfan (2007), and Gelfan et al. (2015) used a
27 physically-based distributed hydrological model in combination with a weather generator to create a long-term probabilistic
28 forecast of spring runoff of rivers in Central Russia. Caraway et al. (2014) incorporated a stochastic weather generator into
29 the ESP to make a probabilistic seasonal climate forecasts and applied the modified methodology to the San Juan River
30 snowmelt-dominated basin. Beckers et al. (2016) used ENSO-conditioned weather generator to compensate for the reduction
31 of ensemble size in the post-processing ensemble forecast scheme presented for the Columbia River basin.

32 The studies and examples mentioned above serve as the background, and the still existing knowledge gaps drive the main
33 motivation for this study. The objective of this study is to contribute to the EPS-related studies, with the focus on the

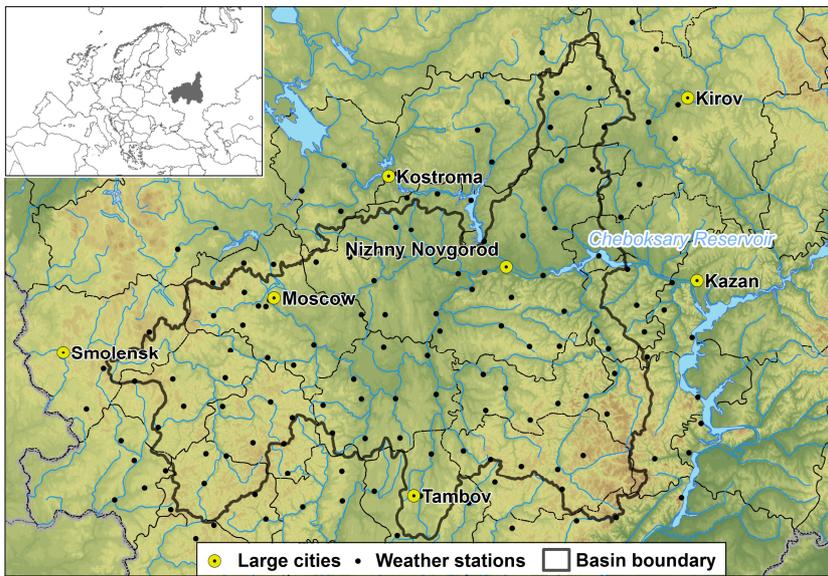

1 comparison between the data-driven techniques used in operational forecasts, and the ensemble forecasts of streamflow,
2 using two different weather scenarios: a) based on the historical data, and b) employing the WG-based forecasts. The case
3 study is the Cheboksary reservoir of the VKRC cascade for which the operational forecasts are available since 1982.

4 Thus, this study is an attempt to answer the following two research questions: (1) Does the model-based ensemble
5 methodology allow one to improve reliability and skill of the operational forecast of spring inflow into the Cheboksary
6 reservoir, and to what extent? (2) Does the enlarged ensemble size lead to any noticeable advantage when using the WG-
7 simulated ensemble compared to the ESP-based ensemble?

8 The remaining part of this paper is organized as follows. The case study is described in the next section. The operational
9 forecast methodology, as well as the proposed forecasting approach including modelling tools (hydrological model and
10 stochastic weather generator), forecasting schemes, experimental design and forecast verification measures are described in
11 Section 3. Results and discussion are presented in Section 4. The overall conclusions and recommendations are given in
12 Section 5.

13 2. Case study basin

14 The Cheboksary reservoir is located on the Volga River in central part of the European Russia. It was constructed in 1982 to
15 become the 11th member of Volga-Kama reservoir cascade with Nizhegorodskoe reservoir upstream, and Kujbysevskoe
16 reservoir downstream of it. Total unregulated basin area of the Cheboksary reservoir is 373 800 km² (Fig. 1). Its main
17 tributaries - Oka, Sura and Vetluga Rivers - account for 80 to 90% of annual inflow into the reservoir.

18
19 **Figure 1: Cheboksary reservoir basin: topography, river network, weather stations**

1 Local climate conditions can be described as moderately continental, with cool snow-abundant winter and relatively hot
 2 summer. Mean annual temperature ranges from 1.4°C in the northern part of the basin to 4.8°C in the southern part. During
 3 wintertime air temperature may fall as low as -35 - -40°C. Annual precipitation amount ranges between 650 and 750 mm
 4 throughout the territory. Around 60% of the precipitation occurs as rain. Most of winter precipitation is stored as snow cover,
 5 emerging in mid-December and lasting until mid-April. Snow water equivalent ranges from 50 mm in the South-Western
 6 part up to 100 – 120 mm in the North. Springtime snowmelt contributes to high-flow freshet – the dominating hydrological
 7 season accounting for around 65% of the total annual inflow into the reservoir (51.3 km³). Typically, freshet commences
 8 around mid-April and lasts until June. Mean volume of inflow for the period of reservoir operation (1982-2016) is 33.4 km³,
 9 mean maximum inflow discharge is 9355 m³/s.

10 3. Method

11 3.1 Operational data-driven forecast of spring inflow into the Cheboksary reservoir: current practice

12 Methodology for forecasting the spring inflow into the Cheboksary reservoir was developed by E.P. Chemerenko (1992) on
 13 the basis of so-called physical-statistical approach originally proposed for the reservoirs of Middle Volga in mid-1960s
 14 (Zmieva, 1964; Gelfan and Motovilov, 2009). This approach is currently in use by the Russian Hydrometeorological service
 15 (Roshydromet) for inflow forecasting into all reservoirs located on the Middle Volga River.

16 Water inflow volume Y into the Cheboksary reservoir is forecasted according to the linear equation:

$$17 \quad Y = \sum_{i=1}^5 \alpha_i y_i + \beta \quad (1)$$

18 where y_i is the runoff forecast at streamflow gauge i , located on the reservoir tributaries: $i=1$ – Oka River, Polovskoe gauge
 19 (drainage area $F=99000$ km²), $i=2$ – Klyazma River, Kovrov gauge ($F=24900$ km²), $i=3$ – Vetluga River, Vetluzhsky gauge
 20 ($F=27400$ km²), $i=4$ – Sura River, Poretsky gauge ($F=50100$ km²), $i=5$ – Tsna River, Knyazhevo gauge ($F=13600$ km²), α_i ,
 21 β – regression coefficients estimated from the streamflow data observed at the corresponding gauge.

22 The runoff volume y_i at i th gauge is forecasted by a unified procedure. The predictors are: basin averaged snow water
 23 equivalent (S , mm), soil freezing depth, (FD , cm), soil moisture index (W , dimensionless) on a forecast issue date, and total
 24 precipitation (x , mm) during the forecast horizon.

25 Runoff volume at each gauge is calculated as follows:

$$26 \quad y = (1 - f) \left\{ (S_1 + x) - P_0 \left[1 - \exp \left(\frac{S_1 + x}{P_0} \right) \right] \right\} + f\eta(S_2 + x) \quad (2)$$

$$27 \quad P_0 = a \exp \left[-b(\theta - \theta_{\min})^c \right] \quad (3)$$

1 where S_1 , S_2 are the snow water equivalent at the forecast issue date within the deep frozen ($FD \geq 60$ cm) and non-deep frozen
2 ($FD < 60$ cm) parts of the river basin, respectively, derived from snow observations; x is the total precipitation for the forecast
3 horizon, assigned as climatic mean; f is the fraction of the basin area covered by deep-frozen soil, derived from soil freezing
4 observations; θ is the soil moisture index, calculated from precipitation amount during the preceding autumn period; η is
5 the runoff coefficient from the basin fraction with non-deep frozen soil calculated as a function of θ ; a , b , c , θ_{\min} are the
6 parameters derived from hindcasts for the 30-year period before the reservoir filling in 1982.

7 The operational forecast of water inflow volume into the Cheboksary reservoir for April-June period is issued just before the
8 beginning of this period (March 27) and then updated 2-3 times during April-May. In this paper, the operational
9 deterministic forecast (not updated, i.e. issued before the beginning of April) is compared with the deterministic forecast
10 derived from the model-based ensemble-mean forecast described below (see subsection 3.2.2).

11 **3.2 Model-based ensemble forecast technique and verification measures**

12 **3.2.1 Modelling tools**

13 *Hydrological model*

14 The ECOMAG (ECOLOGical Model for Applied Geophysics) is a semi-distributed process-based hydrological model
15 describing snow accumulation and melt, soil freezing and thawing, water infiltration into unfrozen and frozen soil,
16 evapotranspiration, thermal and water regime of soil, overland, subsurface and channel flow on a daily time step (Motovilov
17 et al., 1999). The model accounts for measurable watershed characteristics such as surface elevation, slope, aspect, land
18 cover and land use, soil and vegetation properties. The parameters are spatially distributed by partitioning the watershed into
19 sub-basins (elementary basins). Parameterization of the sub-grid processes is described by Motovilov (2016). The model is
20 driven by time series of daily air temperature, air humidity and precipitation intensity.

21 The model was applied earlier for hydrological simulations in many river basins with highly varying sizes and characteristics
22 - from small-to-middle size European basins (Gottschalk et al., 2001) to the large Volga, Lena, Mackenzie with watershed
23 areas exceeding a million km² (Motovilov 2016; Gelfan et al., 2017).

24 In this study, 1x1 km spatial resolution DEM was used for the basin discretization and river network construction. A total of
25 1045 elementary basins were delineated, with average area of 340 sq. km. The model forcing data for each elementary basin
26 were interpolated from the 157 weather stations data (see Fig. 1) employing the inverse-distance method. Most parameters
27 are physically meaningful and were derived through available measurements of the basin characteristics (topography, soil
28 and vegetation properties).

29 The model was calibrated and validated against the Cheboksary reservoir daily water inflow observations beginning from
30 January, 1, 1982 (the 1st year after the reservoir filling to capacity) to December 31, 2016: calibration covered the period of

1 2000-2010, the rest of the data were used for the model evaluation. The ECOMAG calibration procedure is described in
2 detail by Gelfan et al. (2015). It is worth emphasizing two specific aspects concerning this procedure. First, the values of
3 several key parameters pre-assigned from literature or from the available measurements are considered as the initial
4 approximations of the optimal values, and the latter are sought within the neighborhood of the initial, pre-assigned values.
5 Second, during the calibration process, the ratios between the initial values of the distributed parameter corresponding to
6 different soils, landscapes and vegetation are preserved. This approach allows for bringing in the important hydrological
7 knowledge into the optimization procedure. The Nash and Sutcliffe (1970) efficiency criterion NSE is adopted to represent
8 the goodness of fit of the simulated and measured variables.

9 *Multi-site weather generator (MSFR_WG)*

10 The Multi-Site FRagment-based stochastic Weather Generator (MSFR_WG) is the stochastic model using Monte-Carlo
11 simulation to generate time-series of daily weather variables (precipitation, air temperature and air humidity deficit),
12 retaining statistical properties, both spatial and temporal, of the corresponding observed variables. This modeling procedure
13 is based on the so-called “spatial fragments’ (SFR) resampling method” initially presented by Gelfan et al (2015). The SFR-
14 method is a modification of the temporal fragments’ (TFR) method proposed by Svanidze (1980) for stochastic simulation of
15 highly autocorrelated time-series.

16 The SFR resampling method includes the following steps:

- 17 1. Computation of N normalized fields (“spatial fragments”, SFR) of weather variables on the basis of the available
18 meteorological data. SFRs are computed for each of N years of observations by dividing each daily value of the
19 specific variable by the corresponding spatially averaged annual value.
- 20 2. Monte-Carlo simulation of synthetic time-series of M spatially averaged annual weather variables reproducing
21 temporal statistical features of the corresponding annual variables derived from observation data. Cross-correlation
22 between annual values of the simulated weather variables is taken into account through the Cholesky's
23 decomposition method (see e.g. Press et al., 2007).
- 24 3. Calculation of the synthetic daily fields of weather variables by multiplying the computed SFRs (see step 1) by the
25 Monte-Carlo-simulated spatially averaged annual value of the corresponding variables (see step 2). SRFs are
26 randomly chosen from the available set by the Latin Hypercube method (McKay et al., 1979).

27 The advantage of MSFR_WG is that it has a small number of free parameters in comparison with the widely used multi-site
28 weather generators (see, e.g. Khalili et al. (2011) and references therewith), and does not require complex estimation
29 procedures. Such features typically indicate that the model has high robustness.

1 3.2.2 Ensemble forecasting technique

2 The proposed ensemble forecasting procedure utilized in this study was verified by producing hindcasts of water inflow into
3 the Cheboksary reservoir from the 1st of April for 3 months ahead (up to 30th of June). The hindcasts cover a 35-year period
4 between 1982 and 2016. (Hereafter, we use the term “forecasts” for these hindcasts). For each i -th year of the verification
5 period ($i=1, 2, \dots, 35$), the procedure consists of the following steps:

- 6 (1) Spin-up ECOMAG-based simulations (“warm start”) using meteorological observations data prior to the
7 forecast issue date (March, 31) in order to calculate the initial watershed hydrological state (soil, snow and
8 channel water contents, groundwater level, soil freezing depth, etc.) that initializes the forecast. The
9 simulations start from the end of the previous freshet, i.e. 8-9 months before the forecast issue date;
- 10 (2) Selection of a weather scenario¹ from the N_{EPS} -member ensemble of the observed weather or from the N_{WG} -
11 member ensemble of the generated weather for the forecast horizon ($N_{EPS}=51$; $N_{WG}=1000$, see section 4.3.1)
- 12 (3) Simulating daily inflow hydrograph by the ECOMAG model driven by the selected scenario;
- 13 (4) Repetitive selection of the next weather scenario (step 2) from the ensemble and calculation of the
14 corresponding inflow hydrograph (step 3). The corresponding ensemble of N inflow hydrographs is formed (N
15 $=N_{EPS}$ or $N=N_{WG}$);
- 16 (5) From each of the modelled hydrographs, the following inflow characteristics are derived: (1) inflow volume
17 (hereafter referred to as W), (2) maximum inflow discharge (Q_{max}), (3) number of days with the inflow
18 discharge above the mean observed discharge for the forecast horizon (N_q), (4) number of days with the inflow
19 discharge above the mean maximum observed discharge for the forecast horizon (N_{qMax}).
- 20 (6) Deterministic (ensemble mean) and probabilistic forecast are derived and verified for each of the inflow
21 characteristics.

22 3.2.3 Verification measures

23 To verify deterministic and probabilistic model-based forecasts, as well as to compare them with each other and with the
24 operational data-driven forecast of water inflow into the Cheboksary reservoir, we used the following, quite traditional,
25 measures of the forecasts’ efficiency and skill.

26 For the deterministic forecast verification, the mean error (ME), relative bias (BIAS), root-mean-squared error (RMSE), and
27 Pearson’s correlation coefficient R were used. In addition, for presentation, we used the Taylor diagram (Taylor, 2001)

¹ Hereafter, by “weather scenario” we mean an array of weather time-series (daily precipitation amount, air temperature and humidity deficit) that are used to drive the hydrological model for the forecast horizon

1 which combines three forecast characteristics in one chart, namely the forecast standard deviation, RMSE and the correlation
2 coefficient between the observations and the forecasted values.

3 For categorical forecast verification, we used measures that can be calculated from a contingency table (Ferro and
4 Stephenson, 2011), such as probability of detection (POD, shows the correct forecast fraction of the observed events), false
5 alarm ratio (FAR, shows the fraction of forecasts that did not occur), frequency BIAS (shows correspondence of the
6 observed and the forecasted events), Heidke skill score (HSS, shows the advantage of the forecast as compared to a random
7 forecast), Hanssen and Kuipers score (KSS, can detect if the forecast is hedging) and Symmetric Extremal Dependency
8 Index (SEDI, evaluates the performance of the forecast of rare binary events).

9 The probabilistic ensemble forecasts performance was assessed by several verification measures. The ability of forecasts to
10 correctly predict the category of the event occurred within several categories was measured by Ranked Probability Score
11 (RPS) (Wilks, 1995) that can also be treated as the mean squared error of the probabilistic forecast. The probability forecast
12 efficiency relating to streamflow climatology was measured by the Ranked Probability Skill Score (Wilks, 1995). To
13 visualize the specifics of probabilistic forecasts, three diagrams were employed. The predictive Q-Q plot (Laio and Tamea,
14 2007) was used to assess the degree of correspondence between the cumulative distribution function of predictions and the
15 observed values. The reliability diagram (Hartmann et al., 2002) was used to plot the forecast probability against the relative
16 frequency of the observations in the corresponding forecast probability bin. Finally, the discrimination diagram (Wilks,
17 1995) was used to show the frequency of each forecast probability for events and non-events.

18 Full list of the aforementioned verification measures, their formulations, units, and value ranges are presented in Table 1S
19 (Suppl. Materials).

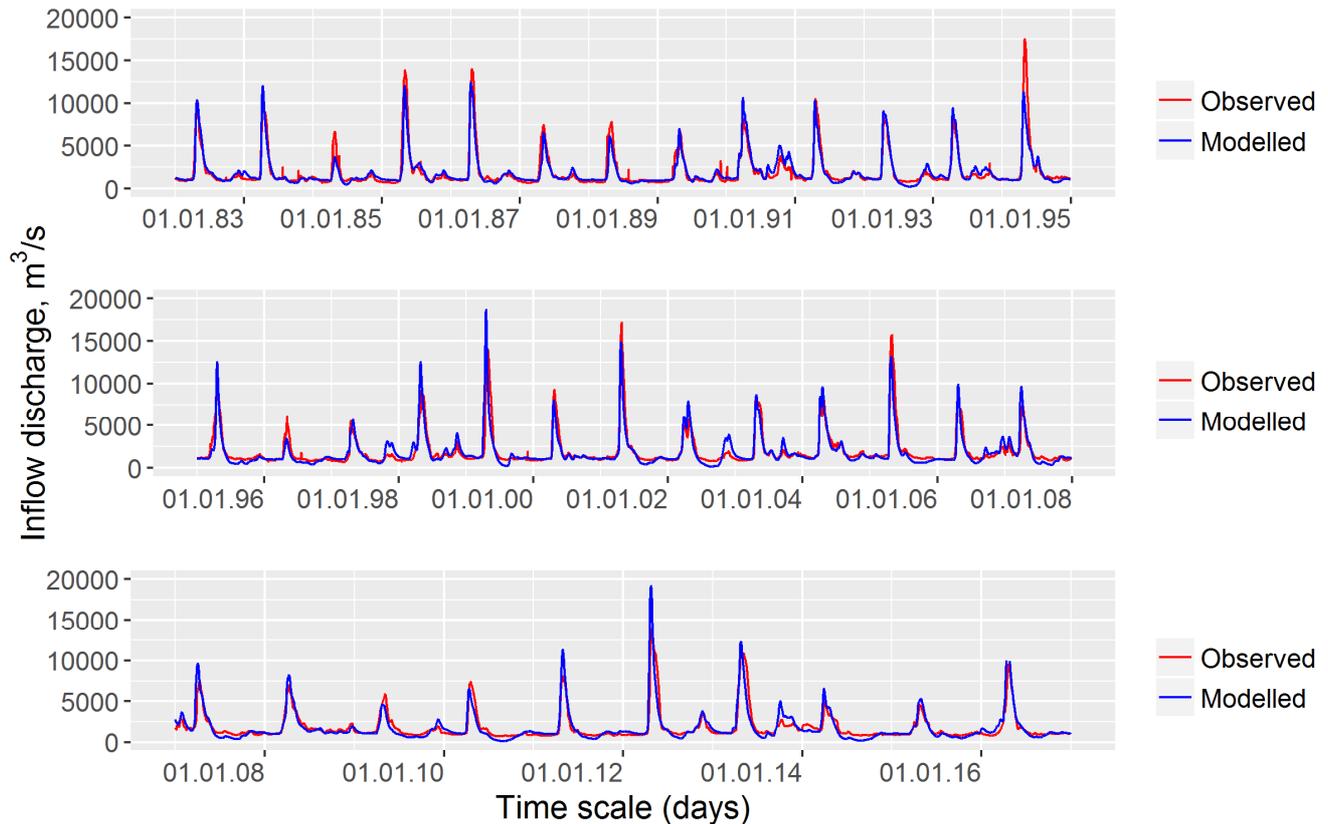

20 **4. Results and discussion**

21 **4.1 Calibration and evaluation of the hydrological model**

22 The hydrological model was calibrated and evaluated against the daily time-series of water inflow into the Cheboksary
23 reservoir for the periods of 2000-2010 and 1982-1999, 2011-2016, respectively. The observed inflow data do not account for
24 inflow from the upstream Nizhegorodskoe reservoir. Fig. 2 compares hydrographs of the observed and the simulated daily
25 inflow discharges. Nash-Sutcliffe efficiency for daily inflow discharge is rather high (NSE=0.80) and ranges from 0.79 for
26 the evaluation period to 0.83 for the calibration one. One can see that the model demonstrates good performance with
27 respect to this criterion. Additionally, a small difference between the criteria estimated for the calibration and evaluation
28 periods confirms the model robustness (Gelfan et al., 2015).

29 The model performance was tested also by comparison of the observed and simulated inflow characteristics, which were
30 used then for the forecast verification and listed in sub-section 3.2.2. Fig. 3 shows scatterplots of the observed and simulated

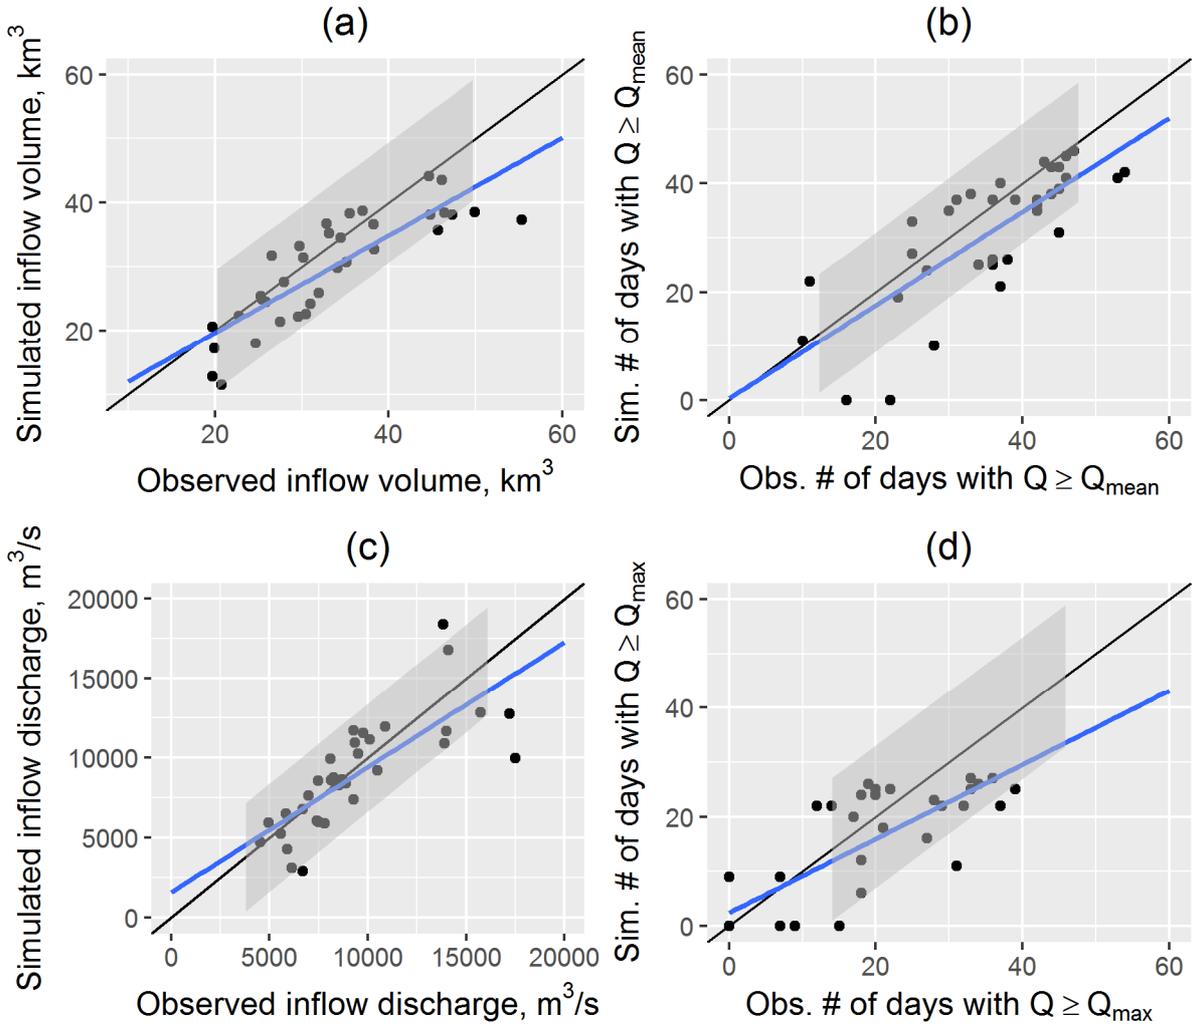

1 characteristics of the inflow into the Cheboksary reservoir in April – June. In general, the inflow volume is well simulated,
 2 yet slightly underestimated for the high flows (above 50 km³, see Fig. 3a). Maximum inflow discharge is a highly uncertain
 3 characteristic, but is still well simulated by the model (Fig. 3c). The number of days above a certain inflow discharge
 4 threshold is a highly important characteristic for various users, e.g. waterways navigation and water supply. For the number
 5 of days above long-term (1982-2016) mean inflow discharge during the period between April and June, the model shows
 6 less days than the observed ones (Fig. 3b) – 31 against 36 days, on average for the whole period. For the number of days
 7 above long-term mean maximum inflow discharge the model also shows less days (Fig. 3d) – 13 against 17 days, on
 8 average.

9
 10 **Figure 2: Observed and simulated daily discharges of inflows into the Cheboksary reservoir**

11 Relative bias (BIAS) of the inflow volume in April – June for the whole period 1982 – 2016 is BIAS=-3%; RMSE of the
 12 inflow volume (5.23 km³) is 55% of the observed data standard deviation ($\sigma_w=9.41$ km³). Relative bias of the maximum
 13 inflow discharge BIAS=5% m³/s; RMSE=2321 m³/s, that is 30% lower than the standard deviation of the observed
 14 maximum inflow discharge (3385 m³/s).

- 1 The obtained results allow us to conclude that the developed model can be considered as a suitable tool for the long-term
 2 hydrological forecast of spring water inflow into the Cheboksary reservoir.

3
 4 **Figure 3: Scatterplots for the observed and simulated characteristics of inflow into the Cheboksary reservoir during April – June:**
 5 **volume W (a), number of days above mean inflow discharge N_q (b), maximum discharge Q_{max} (c), number of days above mean**
 6 **maximum inflow discharge $N_{q\text{Max}}$ (d). Blue line represents linear fit. Black line represent perfect fit. Grey shaded area denotes**
 7 **variance band of ± 1 standard deviation of the respective observed values**

8 **4.2 MSFR_WG: parameter estimation and model testing**

9 Time series of daily precipitation, air temperature and humidity deficit observed at the meteorological stations located at the
 10 Cheboksary reservoir basin for 51 years (1966-2016) are used to estimate the nine parameters of the developed stochastic
 11 model. The parameters estimated by the method of moments are shown in Table 2S in the Supplementary Materials. The
 12 stochastic models were comprehensively tested through their ability to reproduce the main statistical characteristics of

1 meteorological processes at the Cheboksary reservoir basin. For testing, we compared only those characteristics of the
 2 observed and simulated time series, which are neither the parameters of the model, nor a single-valued function of the
 3 parameters as suggested in Gelfan (2010). Statistics of the 1000-member Monte-Carlo generated ensemble of the daily
 4 meteorological variables were compared with the following corresponding statistics derived from observations: mean and
 5 variation of annual and monthly values, autocorrelation functions of daily and monthly values of the specific variables.
 6 Results demonstrating comparison between statistical properties of the observed and simulated series are shown in
 7 Supplementary Materials for spring months and for several selected stations (Figs. 1S-8S).

8 Figs 1S and 8S demonstrate the ability of the developed weather generator to reproduce annual and monthly mean values of
 9 air temperature, precipitation and humidity deficit. Fig. 8S demonstrates good correspondence between the distributions of
 10 the observed and modelled precipitation, as well as Fig. 2S where a good match between the observed and the modelled
 11 coefficient of variation can be seen. Despite some bias, the model errors do not appear to be systematic. The ability of the
 12 generator to preserve the spatial structure of the weather variables was examined by evaluating the spatial correlation curves
 13 (Fig. 7s) for temperature and precipitation, which demonstrate close match for both daily temperature and precipitation.

14 **4.3 Forecast verification**

15 **4.3.1 Ensemble (model-based) and operational (data-driven) deterministic forecasts**

16 We verified the two types of the ensemble forecasts (ESP-based and WG-based), compared them with each other and with
 17 the operational forecasts of water inflow into the Cheboksary reservoir for April-June 1982-2016. To make a deterministic
 18 forecast, the forecasted inflow characteristics were averaged over the corresponding ensembles (51-member in the case of
 19 the ESP-based forecast and 1000-member for the WG-based forecast) to produce a single-value forecast of the desired
 20 characteristic: W , Q_{max} , N_q , N_{qMax} . Operational forecasts of inflow volume for the same April-June periods of 1982-2016 were
 21 obtained from the official Roshydromet forecast bulletins (reports). All forecasts were analyzed to assess the forecast
 22 performance measures: mean absolute error, BIAS, and RMSE. The results are presented in Table 1.
 23

24 **Table 1 – Statistics of the operational (op.) and the ensemble (ESP and WG) deterministic forecasts of inflow into the Cheboksary**
 25 **reservoir for April-June in 1982-2016**

1 * The measure abbreviations are defined in Table 1S

2 First, the deterministic forecasts of the inflow in April-June were compared to the operational forecasts for 1982-2016. As
3 shown in Table 1, the mean error of the operational forecasts appeared to be quite low (around 1%) and close to those of the
4 ESP and WG ensemble average values. However, the operational forecasts RMSE values are significantly higher than those
5 of the ESP and WG forecasts and accounts for almost 70% of the observed inflow volume variability $\sigma_w=9.61 \text{ km}^3$. For the
6 ESP and WG-based forecasts these values are around half of σ_w .

7 Fig. 4 compares the inflow volume forecast errors of the operational forecasts (Fig. 4a) with the ESP-based forecast errors
8 (Fig. 4b). The shaded area in the figures represents the area of the acceptable error $[-0.674\sigma_w; 0.674\sigma_w] = [-6.48 \text{ km}^3; 6.48$
9 $\text{km}^3]$. In the Russian operational forecasting practice, a forecast is considered acceptable if its error falls into this area, and
10 the forecast acceptability is calculated as the ratio of the acceptable forecasts to the whole number of forecasts. According to
11 the assumption of the Gaussian distribution of the forecast errors, 50% of the forecasts by climatology should fall into this
12 interval. It can be seen from Fig. 4 that five of 35 ESP-based forecasts (in 1985, 1994, 2002, 2005 and 2011) and every third
13 (12 of 35) operational forecasts were not acceptable, i.e. the ESP-based forecast acceptability is 89% and that of the
14 operational forecast is 66%. Note that the unacceptable forecasts in both cases occurred in the years with spring precipitation
15 amount notably different from the corresponding climatic mean.

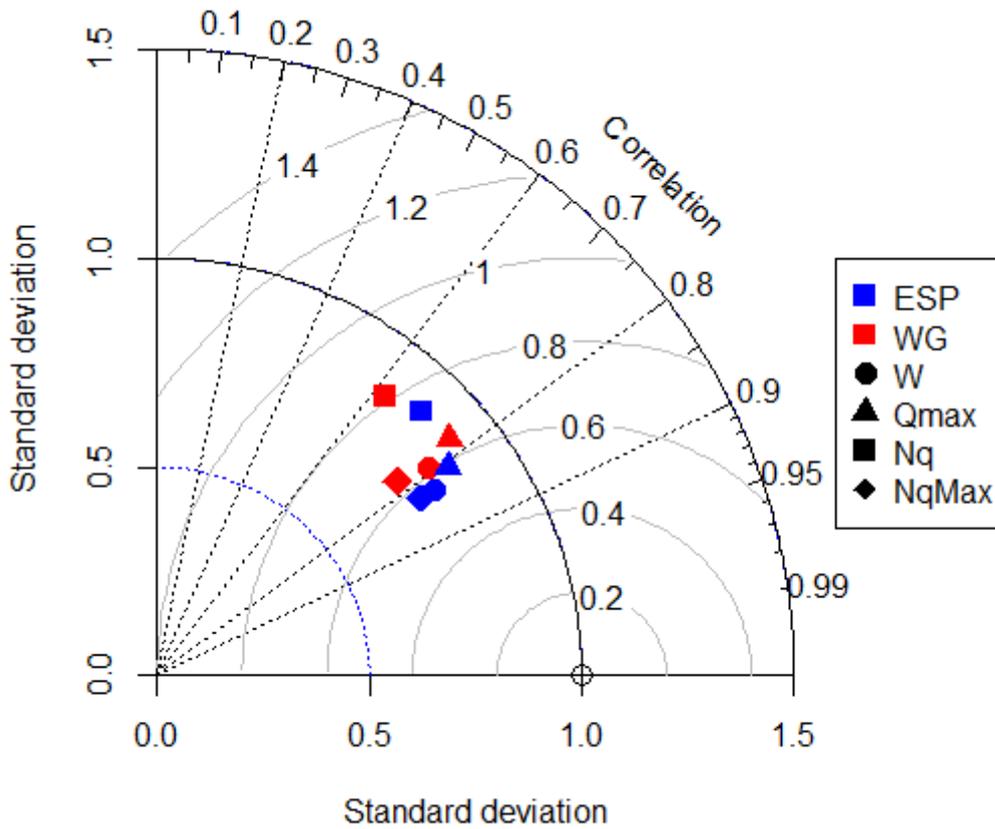

16 To compare the ESP-based and the WG-based forecasts, we present them in the form of the Taylor diagram (Fig. 5; Taylor,
17 2001), which combines three forecast characteristics in one chart, namely, the forecast standard deviation, RMSE and the
18 correlation coefficient between the observed and the forecasted values of the inflow characteristics. The values of all
19 characteristics are normalized by dividing the RMSE by the standard deviation of the observations. This normalization
20 provides a demonstration of the forecast efficiency expressed in fractions of the observed standard deviation. As long as the
21 forecast RMSE is less than the standard deviation of the observations, the forecast can be considered efficient against
22 climatology.

23 It can be seen from Fig. 5 that the ESP-based forecasts of W , Q_{max} and N_{qMax} are slightly better correlated with the
24 observations than the WG-based forecasts. Pearson's R values of the ESP-based forecasts are over 0.8 for all characteristics,
25 except for N_q . Forecasts of N_q are less correlated with the observations, with values of R for ESP-based and WG-based
26 forecasts equal 0.73 and 0.63, respectively. Forecasts of Q_{max} and N_{qMax} show normalized RMSE values around 58-67% of
27 the standard deviation of the corresponding observed characteristics.

 3 **inflow discharge Q_{max} (triangles), number of days with inflow discharge above mean N_q (squares), number of days with inflow**
 4 **discharge above maximum N_{qMax} (diamonds).**

5 For the purpose of reservoir management, it is often crucial to determine whether the expected inflow characteristic will
 6 exceed the corresponding mean value. To verify the methodology capability of predict this exceedance, the observations and
 7 forecasts were converted into binary vectors with “zero” value representing the event of non-exceedance of the mean annual
 8 value and “one” for the event occurrence. For example, for W , the event occurs with the exceedance of mean inflow volume
 9 during April – June. The forecast binary measures assessed with the use of the contingency tables and described in Table 1S
 10 are shown in Table 2.

11 The forecasts show good detection estimates (even perfect for Q_{max}) for both model-based methodologies. However, as the
 12 frequency Bias is high, this might be the result of overprediction, so with the high values of False Alarm Ratio and Hansen-
 13 Kuipers score. For W and Q_{max} , the forecast accuracy with the Heidke Skill Score (HSS) of around 60% is better than the
 14 accuracy of random chance; this means that the forecast is capable of detecting the occurrence of rare extreme events, which
 15 is shown by high values of the Symmetric Extremal Dependency Index (SEDI). Overall, the presented binary verification

1 measures demonstrate a slight advantage of the ESP-based forecasts over the WG-based forecasts, though the differences are
2 not substantial.

3 Binary measures of the operational forecasts of inflow volume are worse than those of the model-based forecasts. For
4 instance, only 69% of the observed events (exceedance of mean inflow volume) are correctly forecasted by the current
5 operational methodology and its accuracy relative to that of random chance is less than 50%. An ability of a user to detect
6 rare events on the basis of the operational forecast is also much lower than with the help of ensemble forecasts.

7 Thus, both continuous (Table 1) and binary (Table 2) model-based forecasts of inflow volume appeared to be more
8 preferable, in general, than the corresponding operational forecasts. However, as one can see from Fig. 4, there were several
9 years, when the operational forecasts were more accurate (in terms of the absolute error) than the ensemble ones. We found
10 that most often the operational forecast outperforms the model-based forecast in those years when the modelled initial snow
11 water equivalent (SWE) on the forecast issue date notably differed from the observed SWE. Since the latter is the main
12 factor affecting the freshet volume, more accurate (observed) initial snow conditions used in formula (2) resulted in more
13 accurate forecast than the one initiated from the simulated SWE.

14 **4.3.2 Freshet of 2017: testing the ensemble methodology**

15 In the beginning of spring 2017, the basin's pre-melt conditions were close to climatology: snow water storage was 10 to
16 15% above the long-term mean value, soil water content and freezing depth were close to the corresponding mean values.
17 However, the weather conditions during the spring freshet formation appeared to be significantly different from climatology.
18 Anomalous warm and sunny weather that settled over the basin in the first half of March has led to commencement of
19 snowmelt and river stage ascent at least half-month earlier than the mean dates. The last decade of March was, on the
20 contrary, cold and damp, and the precipitation amount was twice above normal for this period. As a result, by the end of
21 March the inflow volume (5.13 km^3) into the reservoir exceeded mean March inflow by 32%. Periods of intense snowmelt,
22 interchanged with cold spells and large amount of precipitation, including snowfalls during April and May of 2017 (a
23 number of stations have registered snowfall even in June). Such diversity in weather conditions during the snowmelt period
24 and their difference from the climatology resulted in rather untypical regime of inflow into the Cheboksary reservoir.

25 The ESP-based forecasting technique was tested in operational mode during the freshet period of 2017. The forecasts were
26 issued on March 1st, 15th and 27th for the period from April, 1th till June, 30th. Fig. 6 shows daily forecast ensembles for this
27 period compared to the observed inflow data.

3 * The measure abbreviations are defined in Table 1S

4 ** R is the Range of the measure value

5 *** PFM is the Perfect Forecast Measure value

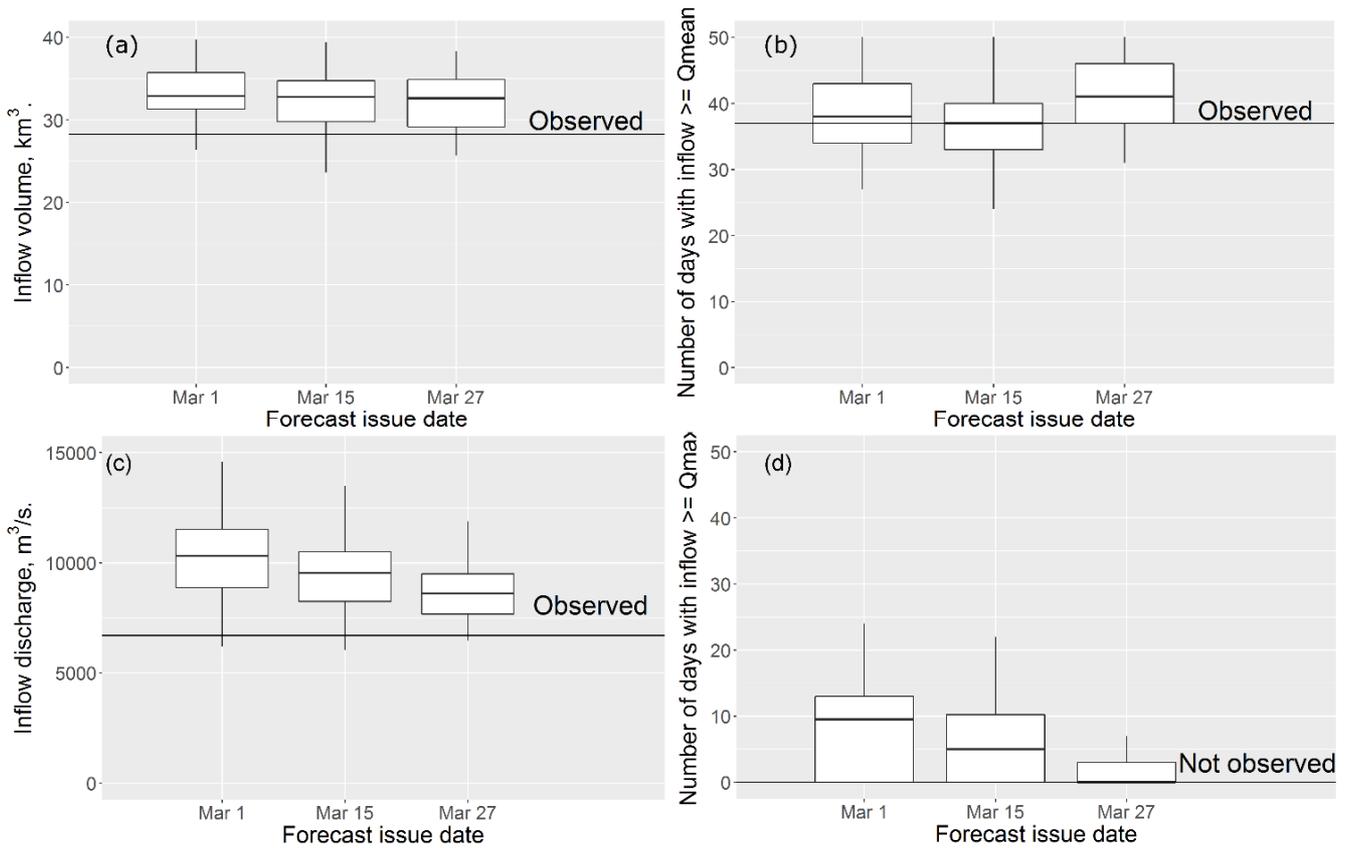

1 Fig. 6 shows the outcome of the anomalous weather conditions that led to earlier increase of the inflow in mid-March (see
 2 panel (a)), which was not captured by the mean ensemble hydrograph of the forecast issued on March 1st. However, several
 3 scenarios of the ensemble show the behavior of inflow similar to the observed one. The forecast issued on March 27th
 4 showed the ongoing increase in inflow discharge, however the colder weather conditions led to inflow stabilization, not
 5 captured by the forecast. One can see visible improvement of the mean ensemble hydrograph issued on March 27th (Fig. 6b)
 6 comparing with the one issued on March 1st (Fig. 6a).
 7

8
 9 **Figure 6: The ESP-based forecast of daily inflow discharge for the period from April, 1st till June, 30th issued on March 1st (a)**
 10 **and March 27th (b). Thin blue lines – ensemble of the forecasted hydrographs; bold blue line – mean ensemble hydrograph, red**
 11 **line – observed hydrograph of inflow into the Cheboksary reservoir.**

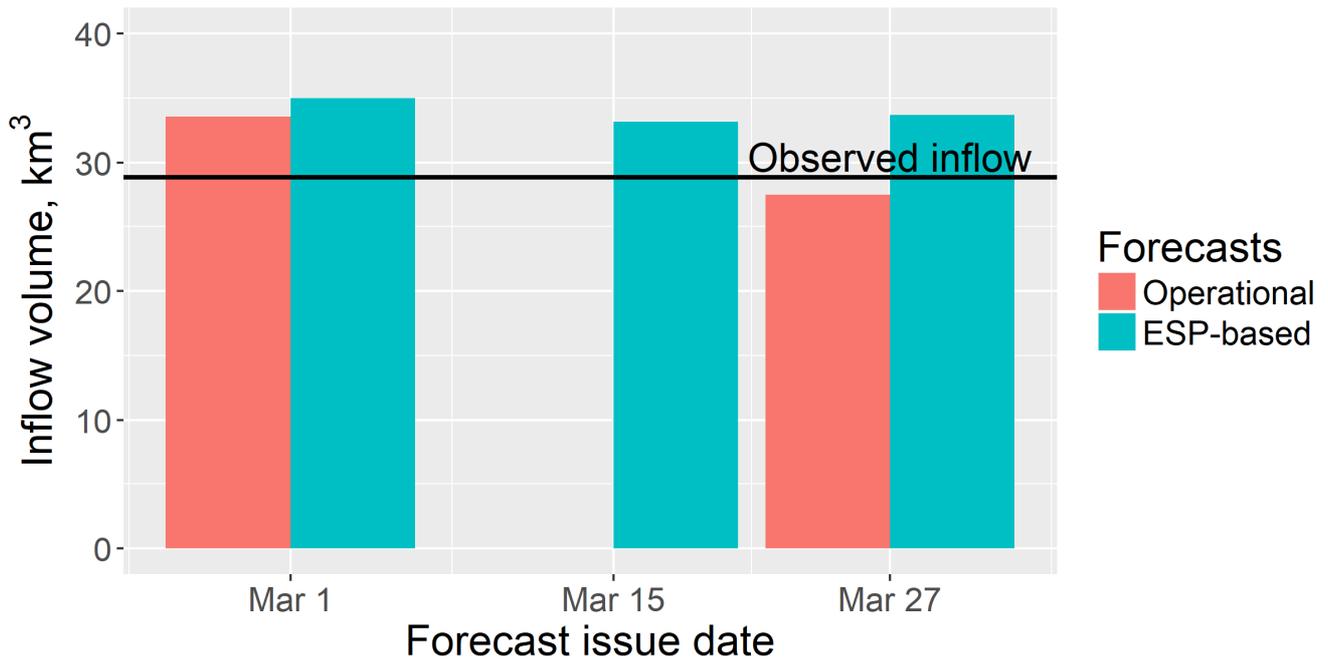

12 Box plots of the ESP-based forecasts of different inflow characteristics are presented in Fig 7. All forecasts of inflow volume
 13 showed low errors (Fig. 7a), unlike the maximum discharge forecasts (Fig. 7b), however, the Q_{max} forecast range envelopes
 14 the observed maximum inflow discharge. Both forecasts of number of days over thresholds showed low errors (Fig. 7b, d),
 15 e.g. just before the beginning of April we correctly forecasted low freshet with the absence of days when inflow discharge
 16 exceeds the mean maximum discharge for the period of observations.

17 In 2017, Roshydromet also issued forecast of spring water inflow into the Cheboksary reservoir on the basis of the
 18 methodology presented above (Fig. 8). In contrast with the results presented in Table 1 and Fig. 4, which demonstrate
 19 general advantage of the ESP-based forecasts over the operational forecasts for 1982-2016, in 2017, the operational forecast
 20 of inflow volume appeared to be better. Possible explanation is again in the simulation errors of the pre-melt SWE used as
 21 initial conditions for the ESP-based forecast.

 3 **01/04/2017-30/06/2017 (line indicates the observed value)**

4 **4.3.3 Probabilistic forecast**

5 In this section, the operational forecast, which is issued in deterministic form only, is not discussed.

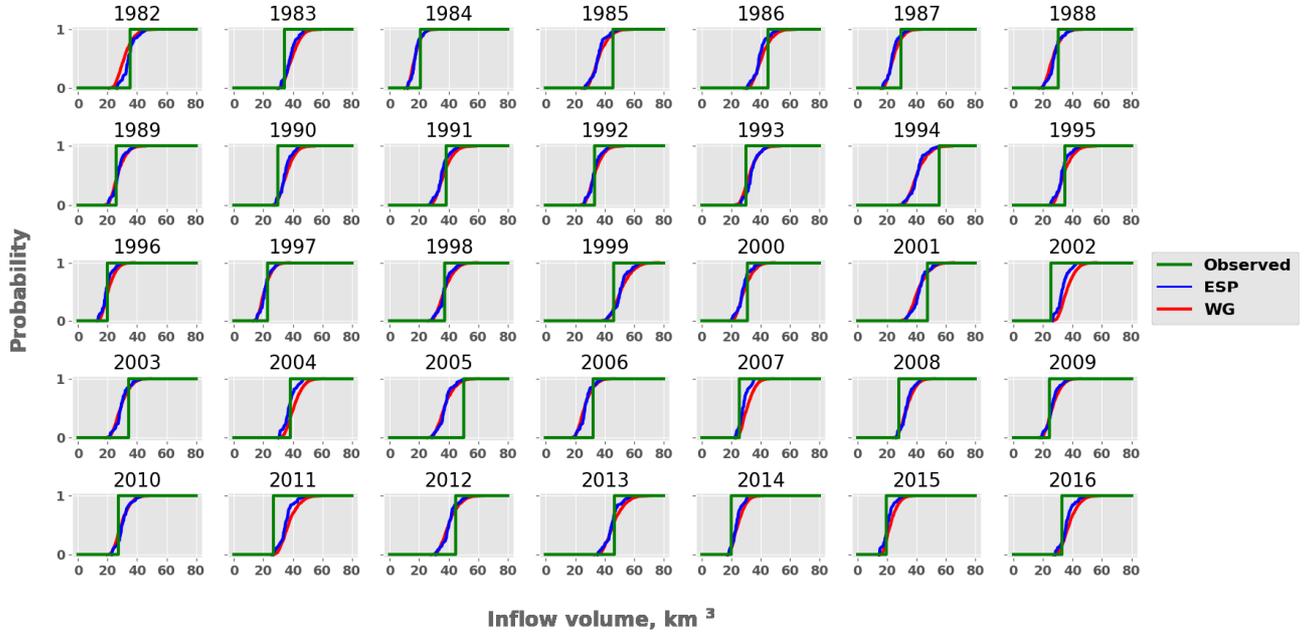

6 One of the main advantages of the ensemble forecasting is the ability to assess the uncertainty that is nested in the future
 7 possible behavior of the hydrological system. The resulting ensemble is used to create cumulative distribution function
 8 (CDFs) of the desired characteristic in j^{th} forecast as

9
$$F_m(j) = \sum_{i=1}^m f_i(j), m=1, \dots, M; j=1, \dots, N, \quad (4)$$

10 where M are the forecast probability bins on the interval $[0;1]$; N – total number of forecasts; f_i – probability of forecast in
 11 m^{th} bin.

12 CDFs of the forecasted inflow volume W for the period from April, 1 to June, 30 of 35 years (1982-2016) are shown in
 13 Fig. 9. Three CDFs are combined in each plot: two CDFs of forecasts calculated under ESP-based and WG-based weather
 14 scenarios, and CDF of the observed inflow volume in the specific year (CDFs of observations can be represented as the
 15 Heaviside step function). One can see from Fig. 9 that for the most of the years the inflow is not far from the most probable
 16 one, in other words, CDF of the forecasts crosses CDF of observations around 50% probability. For almost all years

1 observed inflow lies within the range of the ensemble. Exceptions are 1994, 2002, 2005 and 2011, i.e. once per 8-9 years, on
 2 average, ensemble forecast range does not cover the observed inflow because of large forecast errors.

3
 4 **Figure 9: Cumulative probability distribution functions for W in April – June for all years between 1982 and 2016. Green line –**
 5 **observed inflow, blue – ESP-based forecast, red – WG-based forecast**

6
 7 To quantify the ability of forecasts to predict the probability of an event occurring within the pre-assigned inflow categories,
 8 we used the RPS measure. The forecast efficiency was measured by the RPSS criterion relating the verified forecast to
 9 streamflow climatology (both RPS and RPSS formulations are presented in Table 1S)

10 Both forecasts demonstrate a moderate improvement over climatology: according to the RPSS value, around 30% on average
 11 both for W and for Q_{max} (Table 3). Probably, accounting for a seasonal weather forecast and conditioning historical weather
 12 patterns on this forecast could result in a higher improvement over the streamflow climatology, however a reliable seasonal
 13 weather forecast for the study region is not available.

14 In addition, we compared the ESP-based and the WG-based forecasts by setting the former one as a reference forecast. The
 15 modified RPSS is formulated in this case as:

16
$$RPSS_{\text{modified}} = 1 - \frac{RPS_{WG}}{RPS_{ESP}} \quad (5)$$

1 **Table 3. Ranked Probability Score and Skill Score for the forecasts**

Inflow characteristics	RPS_{ESP}	RPSS (ESP vs. climatology)	RPS_{WG}	RPSS (WG vs. climatology)	RPSS_{modified} (WG vs. ESP)
W	0.33	0.38	0.38	0.28	-0.16
Q_{max}	0.43	0.28	0.49	0.20	-0.13

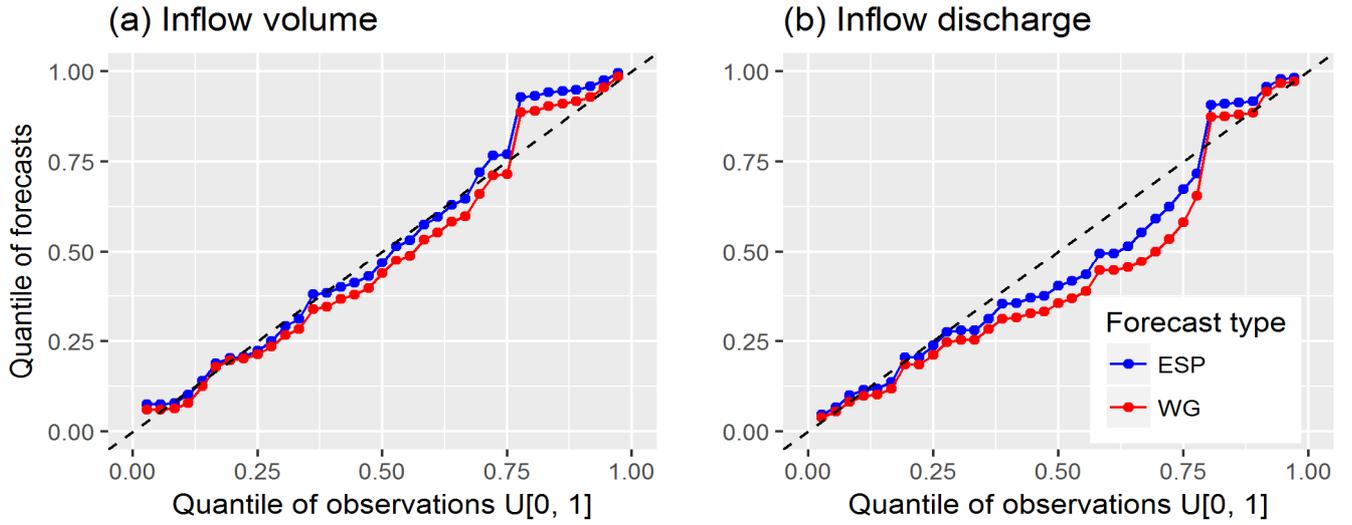

2

3 As one might expect from a comparison of the unmodified RPSS measures, the modified one showed that the WG forecasts
4 are less skillful than the ESP with modified RPSS values of -0.16 for W and -0.13 for Q_{max}.

5 To compare quantiles of the forecasted characteristics with the quantiles of the corresponding observations, we used the
6 predictive Q-Q plot (Laio and Tamea, 2007). As one can see from Fig. 10a, the predictive Q-Q plot of the inflow volume
7 forecasts demonstrates the good agreement with the distribution of the observations. This is fairly consistent for both
8 methodologies and for all quantiles, but for rare events there is an underestimation of the predictive uncertainty, expressed as
9 an offset from the 1:1 line in the upper right corner of the plot. For the maximum inflow discharge (Fig. 10b), one can see
10 overprediction in both methodologies. However, the behavior of ESP-based and WG-based forecasts of rare events is
11 different in terms of predictive uncertainty. Particularly, the WG-based forecasts of the events of low exceedance probability
12 appeared to be closer to the 1:1 line.

13 Additionally, comparisons between the ensemble forecasts of both types can be made based on the reliability and
14 discrimination diagrams presented in Figs. 9S-12S of the Supplementary Materials.

15 Overall, all presented measures of the probabilistic forecast performance are slightly better for the ESP-based forecasts than
16 for the WG-based forecasts, though the differences are not significant and hardly interpretable. At the same time, verification
17 measures obtained from the large ensemble of the WG-based forecasts are expected to be more statistically reliable, which is
18 demonstrated in the next section for the two measures, CDF and RPSS.

1

2 **Figure 10: Predictive quantile-quantile plots for inflow volume (a) and inflow discharge (b) forecasts**

3 **4.3.4 Ensemble size effect on the verification measures: two examples**

4 It can be seen from Fig. 9 that the CDFs appeared to be close to each other for the both ensemble methodologies used.
 5 However, the sample variance of the CDF is significantly different due to different amount of scenarios in the ensembles: 51
 6 in the ESP-based ensemble against 1000 in the WG-based ensemble. To illustrate this difference, we assessed confidence
 7 bands for CDFs derived from both forecasting approaches. A two sided confidence bands were expressed from Dvoretzky-
 8 Kiefer-Wolfowitz inequality as (e.g. Massart, 1990):

9
$$P\left(\sup_{x \in R} |\hat{F}_n(x) - F(x)| \geq \varepsilon\right) \leq 2 \exp(-2n\varepsilon^2) \quad (6)$$

10 where $F(x)$ and $\hat{F}_n(x)$ are the CDF's ordinate and its empirical estimation from a sample of size n , respectively; ε is the
 11 constant depending on the significance level α as

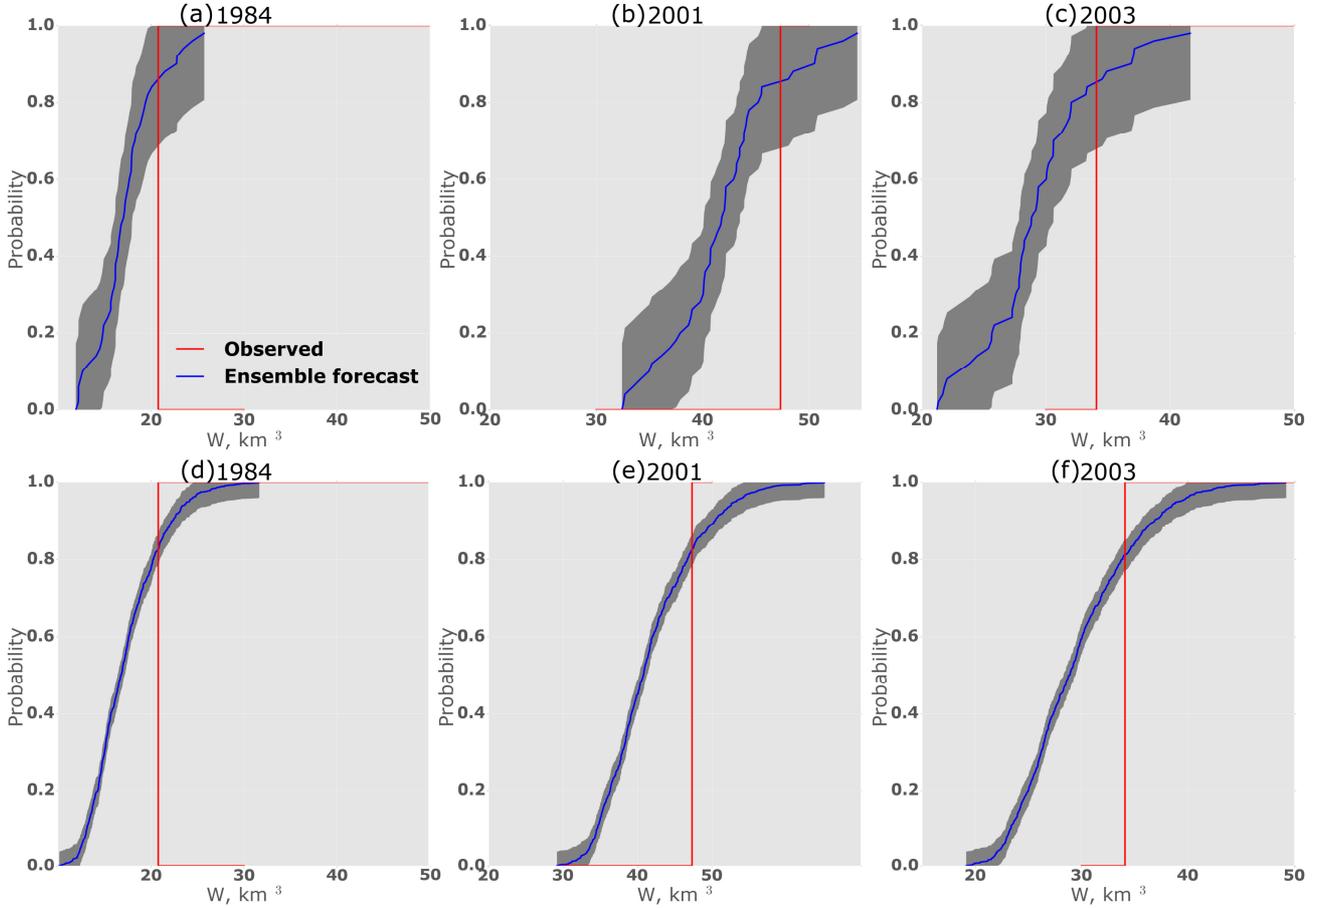

12
$$\varepsilon = \sqrt{\frac{1}{2n} \ln\left(\frac{2}{1-\alpha}\right)} \quad (7).$$

13 For the pre-assigned confidence probability $p=(1-\alpha)$, the upper ($U(x)$) and the lower ($L(x)$) confidence bands of the empirical
 14 CDF $\hat{F}_n(x)$ are defined from (5) and (6) as:

15
$$U(x) = \min[\hat{F}_n(x) + \varepsilon, 1] \quad (8)$$

16
$$L(x) = \max[\hat{F}_n(x) - \varepsilon, 0] \quad (9)$$

1 Fig. 11 demonstrates difference between 95%-confidence intervals of the ESP-based inflow volume forecast as compared to
 2 the corresponding intervals of the WG-based forecast. We believe that the presence of the mentioned difference should be
 3 taken into account by the ensemble forecast developers when they use statistical verification measures for assessment of
 4 forecast performance, as well as by the users when they interpret the forecasts.

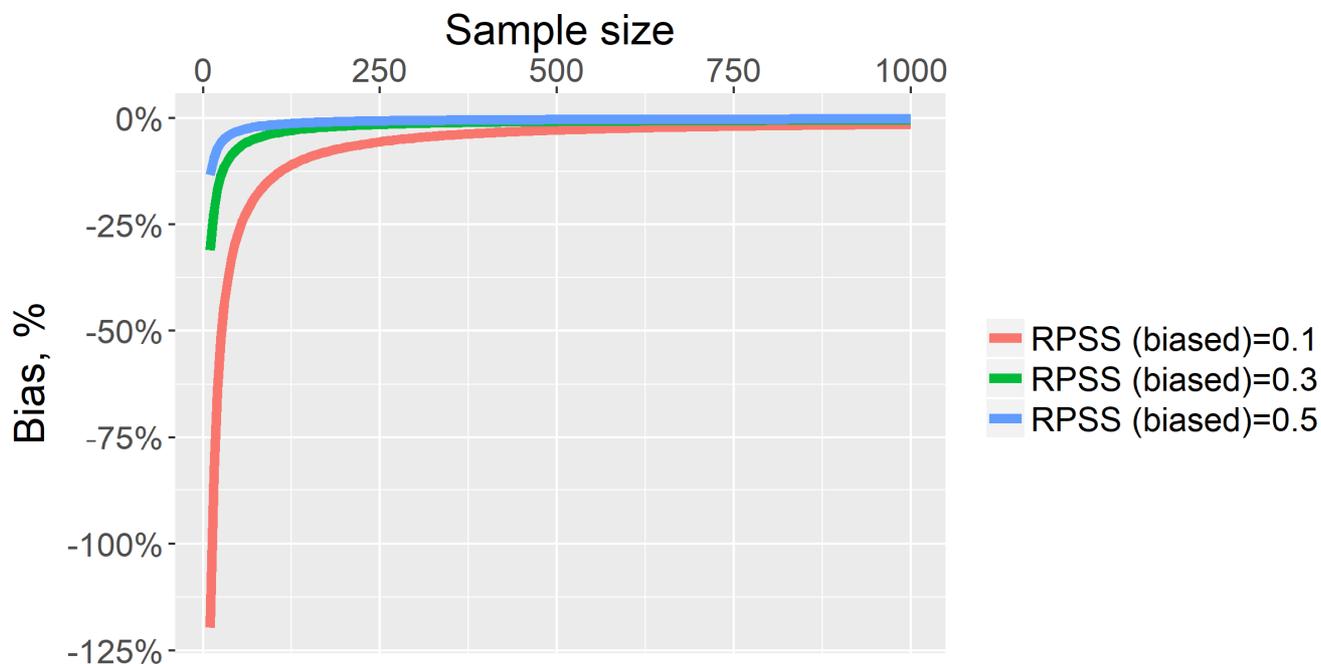

5
 6 **Figure 11: Cumulative probability distribution functions for W in April – June for selected years between 1982 and 2016 for ESP-**
 7 **based forecast (a – c) and WG-based forecast (d – f). Shaded area presents confidence interval of 95% confidence probability.**

8 One can conclude from Table 3 that RPSS criterion demonstrates advantage of the ESP-based probabilistic forecast over the
 9 WG-based one as compared to climatology. However, it is important to take into account that the RPSS measure is strongly
 10 dependent on ensemble size and negatively biased (see, for instance, Müller et al. 2005, Weigel et al., 2007). De-biased
 11 estimate of RPSS can be formulated as by Weigel et al., 2007:

12

$$RPSS_D = 1 - \frac{RPS}{RPS_{ref} + D} \quad (10)$$

1 where D is the correction term depending on the ensemble size, the climatological probabilities, and the number of
2 categories. For very large ensemble size, the correction term D converges toward zero, and the RPSSD - towards the RPSS.
3 Fig. 12 demonstrates the dependence of the RPSS bias on sample size built with the use of approximation of D presented in
4 Weigel et al. (2007).

5
6 **Figure 12: Negative bias of the RPSS-estimate in dependence on the ensemble size and the RPSS value**

7 One can see from this Fig. 12 that under the used 51-member ensemble (i.e. the ESP-based ensemble) the bias can reach tens
8 of percent depending on the RPSS estimate. Under the used 1000-member ensemble, the bias is close to zero.

9 **5 Conclusions**

10 The paper describes the flow forecasting methodology, and the preliminary results of its application to the long-term
11 forecasting of the water inflow into the Cheboksary reservoir, one of the eleven major river reservoirs of the Volga-Kama
12 Reservoir Cascade. The methodology is based on a combination of semi-distributed hydrological model ECOMAG that
13 allows for generating an ensemble of inflow hydrographs using the two different sets of weather ensembles for the lead-time
14 period: the observed weather data constructed on the basis of the ESP methodology, and synthetic weather data simulated by
15 a weather generator. As it is mentioned in the Introduction section, we studied: (1) whether there is any advantage of the
16 developed ensemble forecasts in comparison with the currently issued operational forecasts of water inflow into the
17 Cheboksary reservoir, and (2) whether there is any noticeable improvement in the probabilistic forecasts when using the
18 WG-simulated ensemble compared to the ESP-based ensemble.

1 Our findings can be summarized as follows:

- 2 1. For the 35-year period starting from the reservoir filling in 1982, both continuous and binary model-based ensemble
3 forecasts (issued in deterministic form), outperformed the operational forecasts (currently used in practice) of the
4 April-June inflow volume. However, for several years (including 2017), the operational forecasts were more
5 accurate in terms of the absolute errors. We found that the larger errors of the ensemble forecasts in these years
6 were resulting from the errors in the modelled initial snow water equivalent on the forecast issue date comparing
7 with the observed SWE. The prospects for improving the ensemble forecasts are in assimilation of the observation
8 data (accounting for their reliability) on the forecast issue date. Model-based ensemble approach allows for
9 increasing the number of the forecasted inflow characteristics in comparison with the operational forecast. In
10 addition to the inflow volume for the period of April-June, both ESP-based and WG-based methodology provided
11 acceptable forecasts of maximum inflow discharge, the number of days with inflow discharge above the mean
12 observed discharge, and the number of days with inflow discharge above the mean maximum observed discharge
13 for this period. Thus, the ensemble methodology enhances the information content of the forecast in comparison
14 with the operational one.
- 15 2. Overall, all the presented measures of the deterministic and probabilistic forecast performance are slightly better for
16 the ESP-based forecasts than for the WG-based forecasts, though the differences are not significant and hardly
17 interpretable. At the same time, the verification measures obtained from the large ensemble of the WG-based
18 forecasts appear to be more statistically reliable than the measures obtained from the ensemble size limited to the
19 number of the historical years.

20 Currently we are in the process of fine-tuning the presented forecast methodology for its practical tests during the freshet of
21 2018.

22 In terms of the outlook, it would be beneficial to develop the further research and the corresponding procedures along the
23 following lines:

- 24 1. Refinement of the initial (on the forecast issue date) basin conditions through assimilation of the available
25 observation data (starting with the snow observations) into the hydrological model. Ensemble Kalman filtering is
26 seen as a promising procedure for that (e.g. McMillan et al., 2013; Huang et al., 2016) .
- 27 2. Use of the medium-range and seasonal weather forecasts for developing the additional families of the weather
28 scenarios (both the ESP-based and the WG-based) following, e.g. methods presented by Verkade et al., 2013 and
29 Crochemore et al., 2016. This will allow for increasing the hydrological forecast lead time.
