1 Abstract

2 In a warming climate, the water budget of the land is subject to varying forces such as increasing
3 evaporative demand, mainly through the increased temperature, and changes to the precipitation,
4 which might go up or down.

5 Using a verified, physically based model with 55 years of observation-based meteorological forcing,
6 an analysis of the water budget demonstrates that Great Britain is getting warmer and wetter.

7 Increases in precipitation ($3.0 \pm 2.0 \text{ mm yr}^{-1} \text{ yr}^{-1}$) and air temperature ($0.20 \pm 0.13 \text{ K decade}^{-1}$) are
8 driving increases in river flow ($2.16 \text{ mm yr}^{-1} \text{ yr}^{-1}$) and evapotranspiration ($0.87 \text{ mm yr}^{-1} \text{ yr}^{-1}$), with no
9 significant trend in the soil moisture.

10 The change in evapotranspiration is roughly constant across the regions whereas runoff varies
11 greatly between regions: the biggest change is seen in Scotland ($4.56 \text{ mm yr}^{-1} \text{ yr}^{-1}$), where
12 precipitation increases were also the greatest ($5.4 \pm 3.0 \text{ mm yr}^{-1} \text{ yr}^{-1}$) and smallest trend (0.29 mm yr^{-1}
13 yr^{-1}) is seen in the English Lowlands (East Anglia and Midlands), where the increase in rainfall is not
14 statistically significant ($1.1 \pm 0.7 \text{ mm yr}^{-1} \text{ yr}^{-1}$).

15 Relative to their contribution to the evapotranspiration budget, the increase in interception is higher
16 than the other components. This is due to the fact that it correlates strongly with precipitation which
17 is seeing a greater increase than the potential evapotranspiration. This leads to a higher increase in
18 actual evapotranspiration than the potential evapotranspiration, and a negligible increase in soil
19 moisture or groundwater store.

1 1. Introduction

2 Evapotranspiration affects many important physical aspects of the land: the dryness of the soil,
3 vegetation growth, the temperature of the air and the amount of water in the rivers and
4 groundwater reserves. It is therefore important to understand how evapotranspiration responds to
5 changing climate.

6 For Great Britain (hereafter GB), studies based on the National River Water Archive have shown an
7 overall increase in riverflow of $1.6 \text{ mm yr}^{-1} \text{ yr}^{-1}$ over the last five decades (Hannaford, 2015).

8 Meanwhile, an analysis of the meteorological data for the years 1961-2012 has shown an overall
9 increase in potential evaporation for GB over that time of $0.77 \pm 0.77 \text{ mm yr}^{-1} \text{ yr}^{-1}$ (Robinson et al,
10 2017a). With an increase of rainfall at $2.86 \pm 0.65 \text{ mm yr}^{-1} \text{ yr}^{-1}$ (Robinson et al, 2017a) and assuming
11 the evapotranspiration increases roughly in line with potential evaporation (Kay et al, 2013), this
12 would imply an increase in soil moisture or groundwater recharge of about $0.5 \text{ mm yr}^{-1} \text{ yr}^{-1}$.

13 There is uncertainty in two of these estimates: firstly, the riverflow record is based on a sub-set of
14 rivers and the remainder – particularly in the Scottish Highlands which contribute a large portion of
15 the water – is gap-filled using a simple model. Secondly, the actual evapotranspiration may not
16 follow the potential evaporation. The estimate made by Kay et al (2013) was using a simple model
17 with little representation of vegetation processes.

18 To answer the question about how the actual evapotranspiration has changed over the last 55 years,
19 we would ideally have a direct observation of it both at the long term and over a representative
20 large scale. However, evapotranspiration is difficult to measure. Direct observations of evaporation
21 in GB from flux-tower data exist over short time periods or over small areas, but there are no large-
22 scale, long term observations of this elusive flux.

23 Since there are few long term observations of evapotranspiration, the only way to study its evolution
24 and response to changes in climate is by using a model.

25 However, evapotranspiration is also difficult to model as it depends on the trio of soil, vegetation
26 and atmospheric conditions and the interactions between them. Key processes include the
27 availability of soil moisture to plants during dry spells, the response of plants to temperature,
28 sunshine and soil moisture, the intercepted of rainfall by plants. Assumptions about the processes
29 involved and their interactions (see Wang and Dickinson, 2012 for a review of methods) can have a
30 significant impact on the resulting modelled evaporation (see Schellekens et al, 2017 for overview of
31 model differences).

1 A previous study using a simple soil-moisture-stress-based model (Kay et al, 2013) indicated that
2 there has been an increase in evaporation over the last few decades. However, this modelled trend
3 is only due to changes in soil moisture stress and evaporative demand. The overall trend might be
4 altered by other aspects of the vegetation-atmospheric interactions such as rainfall interception and
5 transpiration responses to changes in meteorology and soil moisture stress.

6 In this paper, a comprehensive land surface model will be used to diagnose the changes in
7 evapotranspiration in GB over 55 years (1961 to 2015) including the analysis of the different
8 components of evapotranspiration (bare soil, transpiration, interception).

9 The questions that will be addressed are as follows:

- 10 1. Is the evaporation of GB and the regions increasing or decreasing?
- 11 2. Which components of the evaporation are contributing to the trend?
- 12 3. What meteorological changes are driving these changes?

13 In Sect. 2, the model, the ancillary and the driving data will be described before the model outputs
14 are presented which will be evaluated with available data. In Sect. 3, the resulting trends in the
15 model outputs will be analysed to address the three questions formulated above. Sect. 4 then
16 discusses the implications of these results while Sect. 5 presents the conclusions about the study.

17

1 2 Method

2 This study uses a physically-based model (JULES: Joint UK Land Environment Simulator, Best et al,
3 2011, Clark et al, 2011) driven by observation-based driving data for 55 years (see Sect. 2.1). The
4 accuracy of the model will be assessed by comparing to a range of independent datasets (see Sect.
5 2.2 for mean monthly evapotranspiration fluxes based on flux-tower data from 4 contrasting sites,
6 annual regional runoff-data from river-flow data, and Sect. 2.3 for estimates from other large-scale
7 models).

8 2.1 JULES model description and setup

9 The JULES model includes many of the processes that are likely to affect changes in water loss (see
10 Appendix A). It is used here in a new assessment of the GB water balance for the years 1961 to 2015.
11 Figure 1 show maps of the time-average quantities of evapotranspiration, sensible heat, soil
12 moisture and soil temperature and Figure 2 shows the spatial average annual values of runoff,
13 evapotranspiration, soil moisture and soil temperature. The rest of the paper describes the
14 provenance of this figure, and analyses the implications of the results. The model output, ancillary
15 files and meteorological forcing data are collectively referred to as CHESS (Climate, Hydrological and
16 Ecological research Support System).

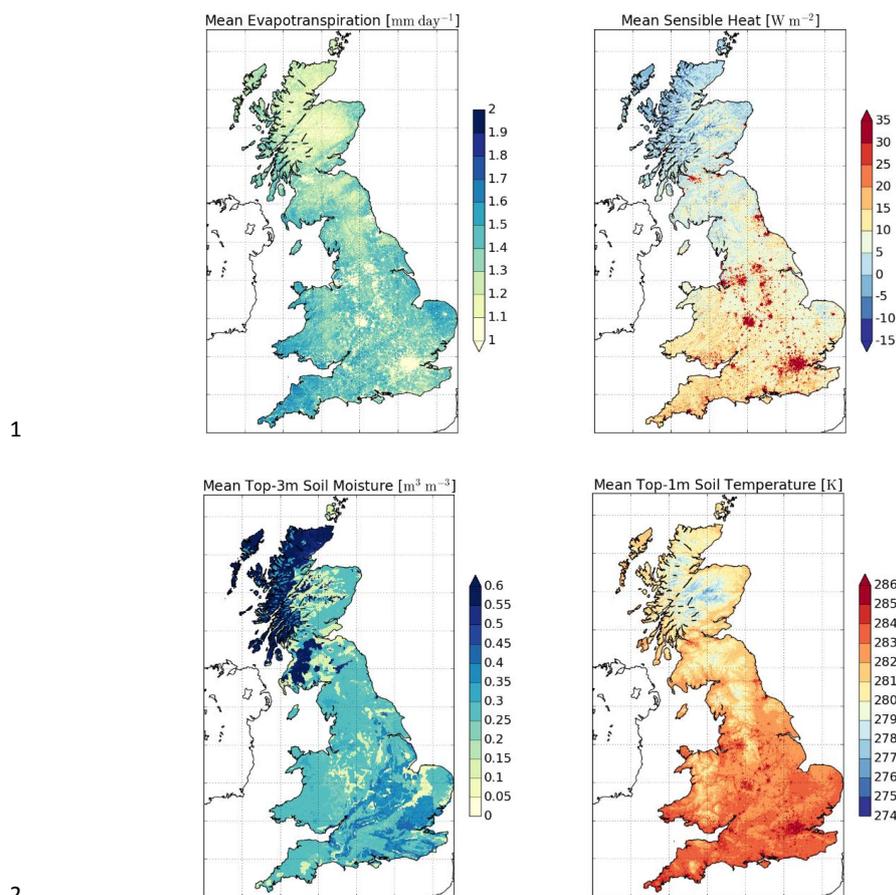

Figure 1. Top and middle rows: Modelled estimates of mean evapotranspiration, sensible heat, soil moisture and soil temperature averaged over 1961 to 2015 for GB.

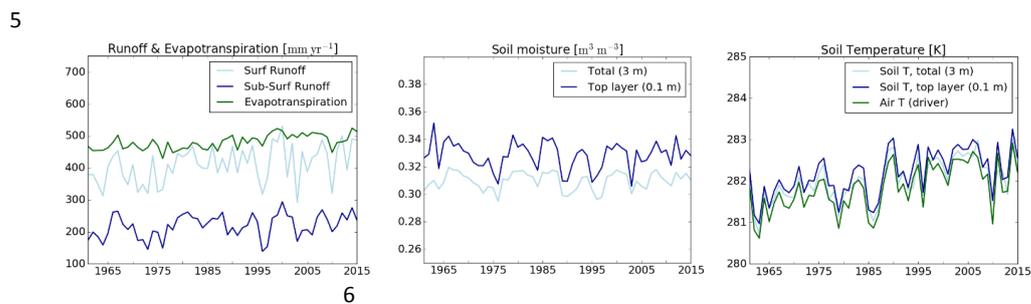

Figure 2. Modelled estimates of runoff, evapotranspiration, soil moisture and soil temperature, averaged over GB against year.

1 Using land cover maps (CEH Land Cover 2000: Fuller et al, 2002), soils maps (Harmonised World Soil
2 Database: FAO/IIASA/ISRIC/ISS-CAS/JRC, 2012) and a newly disaggregated meteorological driving
3 data (Robinson et al, 2017a), the model has been run at a landscape scale of 1 km. This spatial scale
4 is a compromise between being small enough to make reasonable comparisons with observational
5 datasets (such as flux towers), and large enough to be able to obtain reasonable meteorological
6 driving data and with a feasible computer cost.

7 The model used a fixed vegetation map based on observations in the year 2000 (CEH Land Cover
8 2000: Fuller et al., 2002) to prescribe the land cover fractions of the 8 different categories: broad
9 leaf trees, needle leaf trees, grass, crops, shrub, water, bare soil and urban. Parameters values for
10 these land covers are part of the model configuration (see Appendix B).

11 The phenology for each month was prescribed for the deciduous vegetation and the crops. The soil
12 hydrology component of JULES is based on the Darcy Richards equations (see Appendix A for a
13 summary) with the vertical discretization into four layers. The parameters used in the equations
14 depend on the soil type and maps of these were derived from the Harmonised World Soil Database
15 (see Appendix B for a description of their provenance).

16 The meteorological dataset used in the simulations is described in Robinson et al (2017a). This
17 dataset is a combination of daily precipitation based on observations (Gridded Estimates of daily and
18 monthly Areal Rainfall: GEAR: Keller et al, 2006) and other meteorological data from the
19 observation-based product MORECS (Thompson et al, 1981, Hough and Jones, 1997). The MORECS
20 data is presented at 40km and for CHES, the data is downscaled using information about
21 topography. Robinson et al (2017a) analysed the CHES data and showed a positive trend in the air
22 temperature as well as a positive trend in short wave radiation, which is due to increasing short
23 wave radiation in the spring months. The short wave radiation is based on sunshine hours and the
24 CHES data includes a spatially varied impact of aerosol loading that affects the relationship
25 between sunshine hours and short wave radiation. However, it does not explicitly include any time-
26 variation of the aerosols (dimming and brightening). To some extent the dimming and brightening is
27 included implicitly as the sunshine hours are above a certain threshold of intensity, and therefore
28 overall lower light levels will result in fewer hours. This is discussed in more detail in Sect. 4. The
29 data have since been extended to 2015 (Robinson et al, 2017b).

30 The model represents a significant upgrade to the current product available which employed a much
31 simpler water balance model: the Met Office Regional Evaporation Calculation Scheme (hereafter
32 MORECS: Thompson et al, 1981, Hough and Jones, 1997), that does not represent photosynthetic

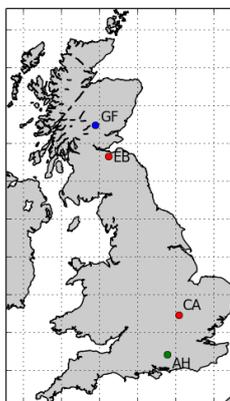

1 processes, has a simple soil-physics routine and runs on a 40 km grid square on a daily time step. The
2 MORECS evapotranspiration is used widely and provides an interesting point of comparison for this
3 new evapotranspiration data product (see Sect. 2.3).

4 2.2 Evaluating the model results with observations

5 This paper makes no attempt to calibrate the model further than has already been done for global
6 simulations. But it is instructive for this analysis to quantify the performance of the model with a
7 standard configuration. Ideally we would be able to evaluate the model with observations at the
8 1km scale with daily or monthly data. However, it is only possible to make direct observations of
9 evapotranspiration using eddy-correlation systems which observe the hourly fluxes over an area of
10 about 100m. At the other extreme, river-flow data can be used in combination with the precipitation
11 to imply the evapotranspiration of a catchment (~100 km) over a year. In this section, the results of
12 the modelled actual evapotranspiration are compared to data from four eddy-correlation systems
13 and the river-flow records of the UK.

14 2.2.1 Evaporation from eddy-correlation systems.

15 There are several flux sites across GB. Out of these, four have been selected, based on the following
16 criteria: a good energy closure, running for several years when the CHES data is available and
17 represents contrasting land cover types (trees and grass) and regional variation (Scotland and
18 England). Their locations are shown in Fig. 3, and Table 1 lists the data that are available, the dates
19 and location coordinates of each site.

20

21 Figure 3: Map showing the positions of the flux sites used for validation. AH=Alice Holt,
22 CA=Cardington, EB=Easter Bush, GF=Griffin Forest. The colours correspond to the vegetation type at
23 the site: green=broadleaf (BL), deciduous, blue=needleleaf (NL), evergreen, red=grass (GR).

	Latitude	Longitude	Years	Land cover at site	% Land cover of CHES square: BroadLeaf, NeedleLeaf, GRass, Shrub, Crop, Urban
Alice Holt	51.1535	-0.8583	1999-2013	BL	36*, 2, 24, 0, 38, 0
Cardington	52.1	-0.416	2005-2011	GR	0, 0, 53.5, 7, 25.5, 14
Easter Bush	55.8660	-3.2058	2003-2005	GR	10, 0, 53.5*, 4, 25, 7.5
Griffin Forest	56.6072	-3.7981	1997-1999	NL	0.5, 91*, 0, 8.5, 0, 0

1 Table 1: Sites used to compare with the CHES data and JULES runs with details of land cover. *

2 indicates the land cover used in the single dominant vegetation cover runs (Fig. 4).

3 As each CHES grid square contains a range of vegetation types, two model results are shown: with
 4 the grid square covered entirely by the vegetation at the site of each flux tower and the grid square
 5 with the fractional vegetation cover as used in CHES (see Sect. 2.1). The original flux data are
 6 measured at 30 minute intervals; the data are checked for quality and gap-filled before daily
 7 averages are calculated. From the daily averages, mean-monthly values are calculated and
 8 presented here.

9 Fig. 4 shows the comparison of the model output with the mean monthly observed data.

1 Figure 4: Climatological monthly average latent and sensible heat fluxes for each of the sites (black
2 solid), compared to the CHES square (green solid), as well as the same square re-run with the single
3 dominant vegetation cover (green dashed).

4 The first thing to note is that CHES tends to simulate higher evaporation than the observations for
5 all of the sites. Following Blyth et al (2010) we compare the evaporative fraction (the ratio of
6 evapotranspiration to the sum of evapotranspiration and sensible heat flux) in Table 2 which allows
7 for equal underestimation of both sensible and latent heat fluxes. In this case, Griffin Forest and
8 Cardington overestimate the total evaporation while Alice Holt underestimates it and Easter Bush is
9 the same. On average however, there is a systematic overestimation of the evaporation in JULES
10 which has been noted previously (van den Hoof et al, 2013) and is discussed in Sect. 3.

11 2.2.2 The seasonality of evapotranspiration

12 Differences in seasonal evapotranspiration between the data and the model are shown in Fig. 4,
13 which highlight some issues with the model, discussed below.

14 For the forest sites (Alice Holt and Griffin Forest) the main discrepancy is in the winter when the
15 model substantially overestimates the evapotranspiration compared to the data: while the
16 observations indicate values of latent heat around zero to 10 W m^{-2} , the model has values of about
17 20 W m^{-2} . In the case of Griffin Forest, the energy for the modelled winter evapotranspiration is
18 coming from the negative sensible heat flux (around -40 W m^{-2} compared to an observed value of
19 around -10 W m^{-2}). In the case of Alice Holt, the negative winter time sensible heat flux is reasonably
20 matched by the observations for the run with single dominant vegetation cover (BL; broad leaf
21 trees). The energy required by the model for the winter evapotranspiration must therefore be due
22 to an overestimate of the net radiation balance.

23 In the case of the grass sites (Cardington and Easter Bush), the winter time fluxes are reasonably well
24 modelled, but the summer modelled evapotranspiration is too high. In Cardington, this
25 overestimation in latent heat is matched by an underestimation of sensible heat. In Easter Bush,
26 there is no simultaneous reduction in sensible heat and therefore energy required for the high latent
27 heat must be due to an overestimate of the net radiation.

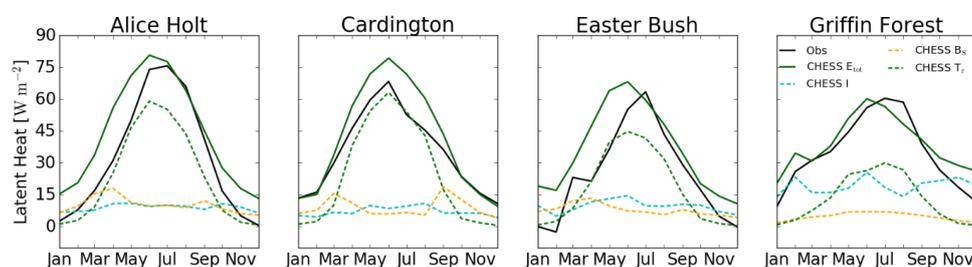

28 The conclusions are the same for both types of model runs (single dominant vegetation cover and
29 mixed vegetation cover), apart from Alice Holt, where the high winter latent heat fluxes are for the
30 BL run. This can be explained by the fact that the CHES square contains substantial fraction of crops
31 and grasses (62% - see Table 1).

1 2.2.3 Analysis of modelled components of evapotranspiration at the flux sites

2 Figure 5 shows the different components of the modelled evapotranspiration (soil surface
 3 evaporation, transpiration and interception). A summary of the results is shown in Table 2.

4

5

6 Figure 5: Seasonal variation in evapotranspiration observed (black solid) and modelled (green solid),
 7 and components – interception (cyan dashed), soil surface evaporation (orange dashed) and
 8 transpiration (green solid).

	Evaporative Fraction as %		P (mm yr ⁻¹)	Transpiration, T _r		Soil surface evaporation, B _s		Interception, I	
	Obs	Model		% E _{tot} total	% P	% E _{tot} total	% P	% E _{tot} total	% P
Alice Holt	88	81	832	54	29	24	13	22	11
Cardington	77	85	562	60	45	22	17	18	13
Easter Bush	77	77	876	50	21	24	9	27	12
Griffin Forest	61	95	1215	35	11	13	4	52	17

9 Table 2: Summary of model results at the four flux sites: Annual average evaporative fraction
 10 (modelled and observed) and precipitation (P). Annual average fluxes of modelled transpiration (T_r),
 11 soil surface evaporation (B_s) and interception (I) as % of total evapotranspiration (E_{tot}) and
 12 precipitation (P).

13 There are no observations of these components at the four flux sites, so it is not possible to evaluate
 14 them directly. However there are estimates of the three components for different vegetation types
 15 in the literature which can be used to assess the model results. In order to translate between the
 16 quoted figures and the model, it is important to note that some authors present the results as the
 17 fraction of the total evaporation and others as the fraction of the total precipitation. For instance,
 18 Van den Hoof et al (2013) summarises work from a range of studies in Europe (Wilson et al, 2001,

1 Verstraeten et al, 2005, and Choudhury and DiGirolamo, 1998), focusses on the former and quotes
2 values of forest interception to range from 13% to 25% of the total evaporation while for grasses it is
3 closer to 10%.

4 Meanwhile, Nisbet (2005) summarises a large body of work by scientists studying interception and
5 transpiration in the UK (Calder, 1990, Calder et al, 2003, Roberts, 1983), focusses on the latter and
6 quotes a percentage of rainfall that is intercepted: about 20% of rainfall for broadleaf trees and 35%
7 for needleleaf. The evidence suggests that the annual fraction of rainfall intercepted by trees is fairly
8 constant across a wide range of annual rainfall regimes, although increases slightly at low annual
9 rainfalls (<500 mm yr⁻¹). The data are sparser for grass and no values are given in this report,
10 although interception rates of heather and bracken are quoted at about 20% of rainfall.

11 The model results in Table 2 confirm the analysis of Nisbet (2005). The fraction of rainfall that is lost
12 through interception is fairly constant over the four sites, ranging from 11% to 17%. This translates
13 into a large fraction of total evaporation that is due to interception: 18% to 52%. At Griffin Forest,
14 the model evaporative fraction is much higher than the observation (95% compared to 61%). 52% of
15 the model evaporation is due to interception. Compared to the Van den Hoof et al (2013) figures of
16 interception, this might be considered to be too high. However, this only represents 17% of the
17 precipitation in this high-rainfall area. Many of the studies from Van den Hoof are in regions with
18 much lower annual precipitation. The value of 17% is low compared to other estimates of
19 interception loss in needle-leaf trees as reported in Nisbet (2005).

20 In the much lower rainfall regime where Alice Holt is sited, the modelled interception is only 22% of
21 the evaporation budget, which is dominated by the transpiration (54%).

22 This analysis suggests that the model has a reasonable representation of interception, capturing its
23 conservative relationship to the precipitation.

24 The transpiration, on the other hand, is more controlled by the available energy and has a more
25 uniform relationship with total evaporation (see Roberts, 1983) ranging from 35% to 60%, and a
26 wider range of fractions of precipitation, from 11% to 45%. The values of transpiration are lower
27 than the values given by Van den Hoof et al (2013) and Nisbet (2005) who quote values for trees
28 from 53% to 70% of total evaporation being due to transpiration. It is possible that the total value of
29 transpiration is reasonable, but the fraction is low due to the overestimation of the total
30 evaporation.

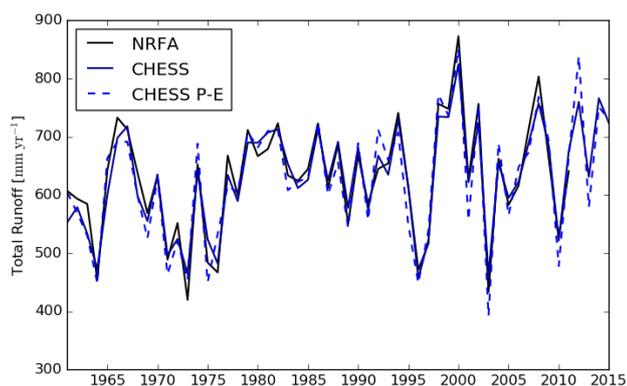

1 The bare soil evaporation compares reasonably well with data quoted in the literature although
2 figures are rather low. The values range from 13% to 24% of the total evaporation and correspond
3 to values quoted in van den Hoof et al (2013) of 20% and 30%. The low bias might be due to the fact
4 that the UK sites are in relatively high rainfall areas with high interception so that even if the total
5 evaporation is correct, the percentage is low.

6 2.2.4 River flow

7 At the annual timescale, changes in water storage in a UK catchment are negligible and the area-
8 average evapotranspiration can be estimated as precipitation minus river-flow. Daily river flow
9 records for the UK are available in the National River Water Archive (NRFA) which is hosted at CEH,
10 Wallingford. A subset of these records have been chosen for their length of record, accuracy, little or
11 quantifiably affected by abstractions. The annual runoff from these catchments is then combined
12 with a model to scale up to the regional and GB scale to present net annual and monthly runoff. The
13 method for this is described in Marsh et al (2015). Hannaford (2015) has summarised the results,
14 which are reproduced here in Figs. 6, 8 and Table 3. The challenge addressed here is to identify
15 whether using a model to fill in the gaps introduces a bias to the results.

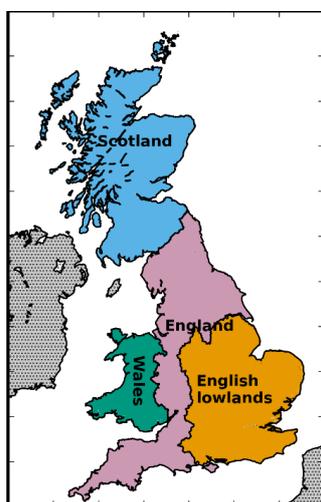

16 Fig. 6 plots the total GB annual river flows from these processed observations. The GB runoff, and
17 precipitation minus the evapotranspiration (the difference being the soil-moisture) from the model
18 is also shown. It is apparent from this figure that the modelled runoff is slightly lower than that
19 observed, which is commensurate with the analysis in the previous sub-section that the modelled
20 evapotranspiration is too high. However, the percentage difference is very small (0.15%) which is not
21 consistent with the previous estimates of the bias (roughly 10%). An analysis of the regions shows
22 where this discrepancy occurs.

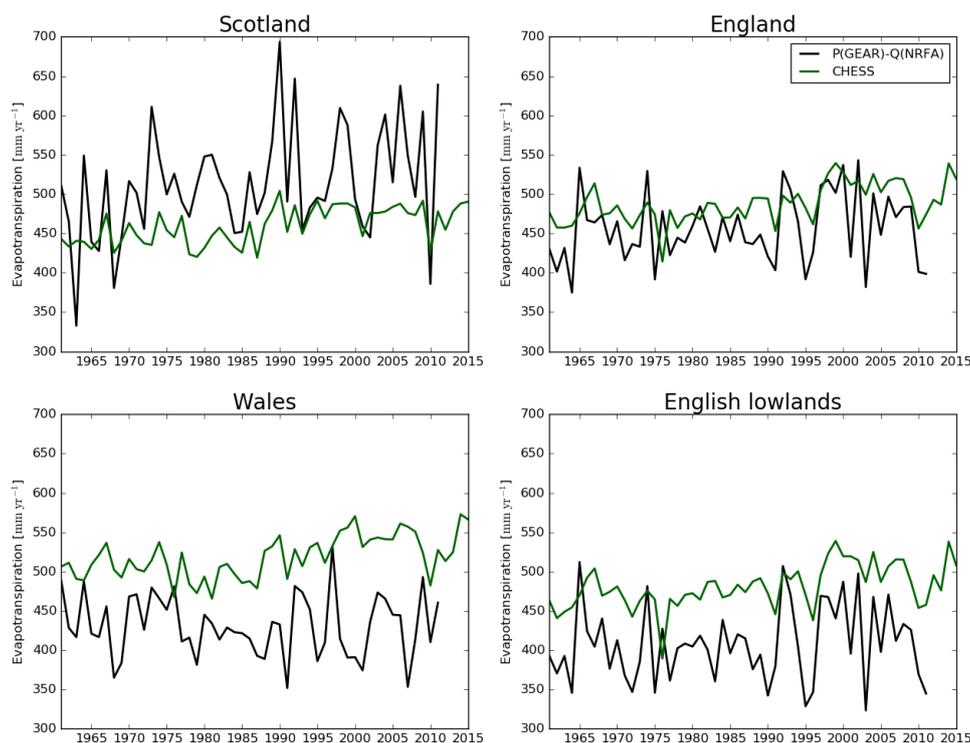

23

- 1 Figure 6. Comparison of CHES annual runoff and precipitation-evaporation (P-E) to the observed GB
- 2 annual river flow (NRFA; data available up to 2011).
- 3 Fig. 7 shows the definitions of different regions used by the NRFA. They represent different GB
- 4 climate types: Scotland is wet and cold, Wales is wet and warm, England is dry and warm, English
- 5 lowlands is very dry and warm (these adjectives are relative to each other, not to a global standard).

- 6
- 7 Figure 7: The four defined regions: green is Wales, blue is Scotland, orange and pink together are
- 8 England, orange alone is the English lowlands.
- 9 Fig. 8 shows the model and observation-based results for evapotranspiration in these regions, while
- 10 Table 3 gives a summary of the annual average values for the regions.

1

2 Figure 8: Annual averages for evapotranspiration in the four regions for CHESSE and precipitation-
 3 runoff (P-Q) observed. Here, the observation-based products used are GEAR for precipitation and
 4 NRFA for runoff.

Annual average (mm yr ⁻¹)	Precipitation	Model Runoff	Observed Runoff	Model Evap.	Observed Evap. (P-Q)	Bias in Evap (% Observed)
Scotland	1485	1032	972	458	513	-10.5%
Wales	1377	863	945	516	432	+19.5%
England	825	342	369	485	456	+4.5%
English Lowlands	681	206	273	479	408	+17.5%

5

6 Table 3: Annual average water balance for the four regions.

7 Table 3 shows that in Wales, England and the English lowlands, the model overestimates
 8 evapotranspiration by 5 to 20%. This corroborates the results of the analysis with the flux data which

1 show an overestimation of about 10%. However, in Scotland the comparison indicates the opposite:
 2 the model has a lower evapotranspiration than the precipitation-runoff product. This anomalous
 3 outcome is probably a result of the way the riverflow observations were sampled and then
 4 extrapolated to the regional scale. As explained above, the estimate is made with 'Index
 5 Catchments' chosen for the length of record (see Marsh et al, 2015), which in the Scottish region are
 6 mainly in the low-lying East of the region. Due to the short record length, the Highland and West of
 7 Scotland runoff data is not used and instead the area contribution was estimated by a model. The
 8 evapotranspiration in this wet region will be near to the potential evapotranspiration (PET), so the
 9 value of PET used in the model will dominate the result.

10 The PET product used for the gap-filling was from MORECS, which is based on observations and
 11 calculated at the 40 km grid-scale. In flat terrain, it is a valid assumption that PET will not vary over a
 12 40 km grid and that it can be used at the 1 km grid-scale. However, in hilly terrain such as western
 13 Scotland, that is no longer the case. As indicated in Blyth (1999), since is it always windier on the
 14 tops of the hills where PET is lower (due to the cold temperatures), the area-averaged PET is lower in
 15 a hilly region than would be implied using topographic-mean data. This may explain the
 16 overestimation of PET and underestimation of the river flows in Scotland in the observation-based
 17 product of Hannaford (2015).

18 If the results for Scotland are ignored, the comparison suggests an overestimate of the model of the
 19 order of 10 to 15%.

20 2.3 Evaluating the model by comparison with other modelled estimates

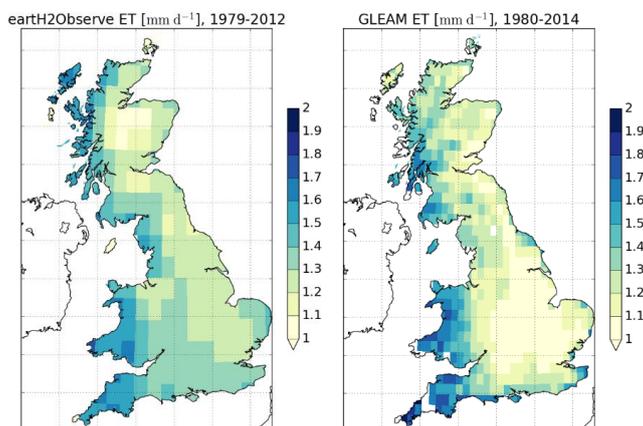

21 There are several available large-scale evapotranspiration estimates to compare to the model. All of
 22 these estimates are model-derived. It is not expected that they will be more accurate than CHES
 23 and this is not an evaluation exercise. However, it is interesting to make the comparison. Table 4
 24 describes the datasets: their derivation and the annual mean evapotranspiration for GB and the four
 25 regions in Fig. 7. They are derived from models of differing complexity, either driven by satellite-
 26 derived data, or ground-based weather data. Fig. 8 shows the maps of the annual mean
 27 evapotranspiration from the four products (CHES scaled up to 40 km, earth2Observe, GLEAM and
 28 MORECS) while Fig. 10 shows how the GB average varies over time.

Product (version)	References	Methods	Annual Evapotranspiration (mm yr ⁻¹)				
			GB	S	W	E	EI

earth2Observe (WRR1)	Schellekens et al (2017)	Ensemble mean of 10 global models (4 land surface models and 6 hydrological models) (see Table 1 in given reference for details)	502	477	546	485	474
GLEAM (v3.0a)	Martens et al (2017) Miralles et al (2011)	Data-driven model (Priestley-Taylor), using meteorological data from reanalysis, satellite and gauged-based global datasets (0.25° resolution)	463	471	568	439	410
MORECS (v4)	Thompson et al, (1981) Hough and Jones (1997)	Data-driven model (Penman-Monteith), using observed GB meteorological data (40 km resolution)	524	482	543	528	522

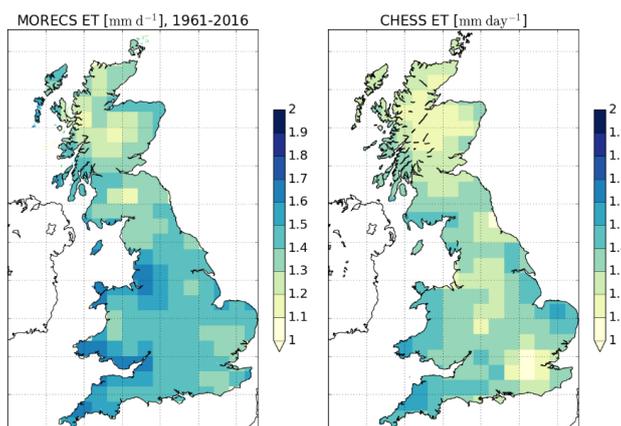

- 1 Table 4: Description of the three large-scale evapotranspiration estimates for GB, and annual
- 2 averages over GB and the four regions: Scotland (S), Wales (W), England (E) and English lowlands
- 3 (EI).

5

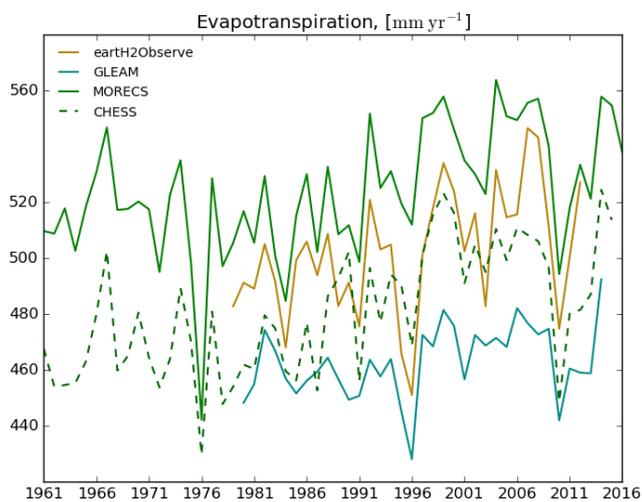

1

2

3 Figure 9: Maps of mean evapotranspiration for earth2Observe, GLEAM, MORECS and CHES
 4 (averaged up to 40 km).

5

6 Figure 10: Annual average evapotranspiration for earth2Observe, GLEAM and MORECS and CHES.

7 It can be seen from the Figs. 9 and 10 and from the Table 4 that the main differences between the
 8 various products is the total evapotranspiration. CHES evapotranspiration is higher than GLEAM
 9 and lower than MORECS, and close to the ensemble product from earth2Observe.

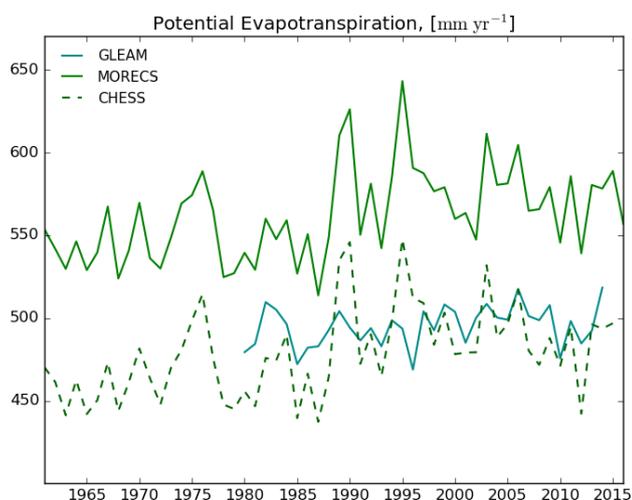

10 To understand the evapotranspiration in all of these estimates, it is important to know the assumed
 11 role and values of PET (or equivalent) in the model. Fig. 11 shows the value of PET for GLEAM,

1 MORECS and CHES (not available for E2O). It is clear from this figure that the MORECS PET is higher
2 than the CHES PET, commensurate with the difference in actual evapotranspiration. This suggests
3 that the difference between CHES evapotranspiration and MORECS evapotranspiration is due to
4 the PET. A comparison of CHES PET with GLEAM PET shows that they have a similar magnitude.
5 This indicates that the reason the GLEAM evapotranspiration is lower is due to model differences,
6 not the PET.

7 This result corroborates the results of the analysis in Schellekens et al (2017) which showed that
8 GLEAM had much lower evapotranspiration than a wide spread of models in the temperate regions.

9

10

11 Figure 11: Annual average potential evapotranspiration for GLEAM, MORECS and CHES.

12 2.4 Summary and discussions of model evaluation

13 The evaluation of the model show that the overall evaporation is overestimated by of the order of
14 10%. In winter, this overestimate is greater for trees than for grass, whereas for grass the
15 overestimate is in the summer. According to analysis of observations, the model underestimates the
16 interception from trees, especially conifer trees.

17 The winter evaporation for deciduous trees tends to be overestimated. This is probably due to the
18 known issue in the model of using a single aerodynamic resistance for the trees and underlying soil
19 surface evaporation.

- 1 Analysis of river flows suggests that the use of a fine grid (1km compared to 40km) for evaluating
- 2 evaporation results in more accurate estimates of the water budget over areas of high terrain.
- 3 Although comparison with observations is not perfect, the model displays reasonable allocation of
- 4 evaporation across the different components compared to observational evidence, and we
- 5 therefore deem it good enough to proceed with the subsequent analysesPETI_

1 3 Results

2 In this section, the results of the model will be used to address the four questions formulated in the
 3 introduction.

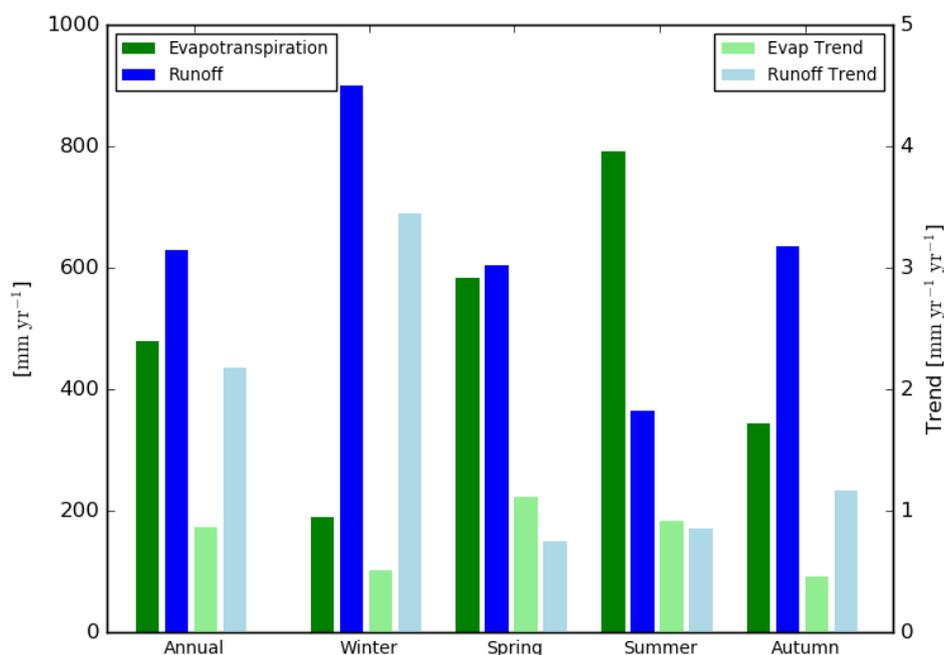

- 4 1. Is the evaporation of GB and the regions increasing or decreasing?
 5 2. Which components of the evaporation are contributing to the trend?
 6 3. What meteorological changes are driving these changes?

7 The analysis starts with a study of annual and seasonal evapotranspiration in GB. Then we move on
 8 to a study of evapotranspiration in the regions of GB (Scotland, Wales, England and English lowlands,
 9 as defined in Fig. 7). These two sections answer the first question. The trends in the different
 10 components of evapotranspiration for whole of GB are quantified to answer the second question.
 11 The third question is addressed by studying the correlation between the evapotranspiration in the
 12 regions and the different drivers of change (precipitation and solar radiation).

13 3.1 Trends in GB water balance: annual average and seasons.

Annual (Seasons: Winter, Spring, Summer, Autumn)	Average	Rate Of Change (units yr ⁻¹)
Precipitation (mm yr ⁻¹)	1106 (1284,896,929,1313)	2.96±2.03 (6.95±6.25, 0.28±2.61, 2.25±4.01, 2.13±4.20)
Evapotranspiration (mm yr ⁻¹)	481 (190,585,794,345)	0.87±0.55 (0.52±1.03, 1.12±0.64, 0.92±0.67, 0.46±0.51)
Runoff (mm yr ⁻¹)	630 (901,604,365,636)	2.18±1.84 (3.45±5.05, 0.75±2.18, 0.86±1.67, 1.17±2.71)
Soil Moisture (m ³ m ⁻³)	1267 (1345,1293,1162,1246)	-0.02±0.77 (-2.50±3.07, -0.33±0.55, 0.05±1.22, -0.02±0.98)
PET (mm yr ⁻¹)	479 (134, 592, 885, 296)	0.74±0.66 (0.20±0.53, 1.37±0.65, 0.96±1.68, 0.38±0.49)
Observed Runoff (mm yr ⁻¹)	629	1.57±2.04

14 Table 5: Annual average and seasonal average fluxes and trends in the fluxes of: Precipitation,
 15 Evapotranspiration, Runoff, Soil Moisture and Potential Evapotranspiration.

1

2 Figure 12: Bar chart showing annual and seasonal water budgets and trends (evapotranspiration and
3 runoff). Trends are represented on the right y-axis.

4 The annual average of total evapotranspiration has been presented and compared to observations in
5 Sect. 2 (Table 3). Here the seasonal variation in evapotranspiration is explored. The seasons are
6 defined as Winter (December to February), Spring (March to May), Summer (June to August) and
7 Autumn (September to November).

8 Table 5 and Fig. 12 show that here is a strong seasonality to the evapotranspiration, with summer-
9 time values over four times the winter-time values. This seasonality is strongly driven by the
10 seasonal variation in PET which has a 6-fold increase from the winter values to the summer values.
11 Soil moisture control reduces the summer evapotranspiration to about 75% of the PET, while the
12 winter and autumn evapotranspiration exceed the PET by on average 25%. The reverse is true of the
13 river flow which responds to a low seasonal variation in precipitation (only 1.35 variation between
14 winter and summer) but exhibit some soil moisture control with summer runoff 2.5 times smaller
15 than winter runoff.

16 The largest trend in evapotranspiration is seen in the spring months ($1.12 \text{ mm yr}^{-1} \text{ yr}^{-1}$). This result
17 corroborates the results of an analysis of PET by Robinson et al (2017a), who demonstrated that the

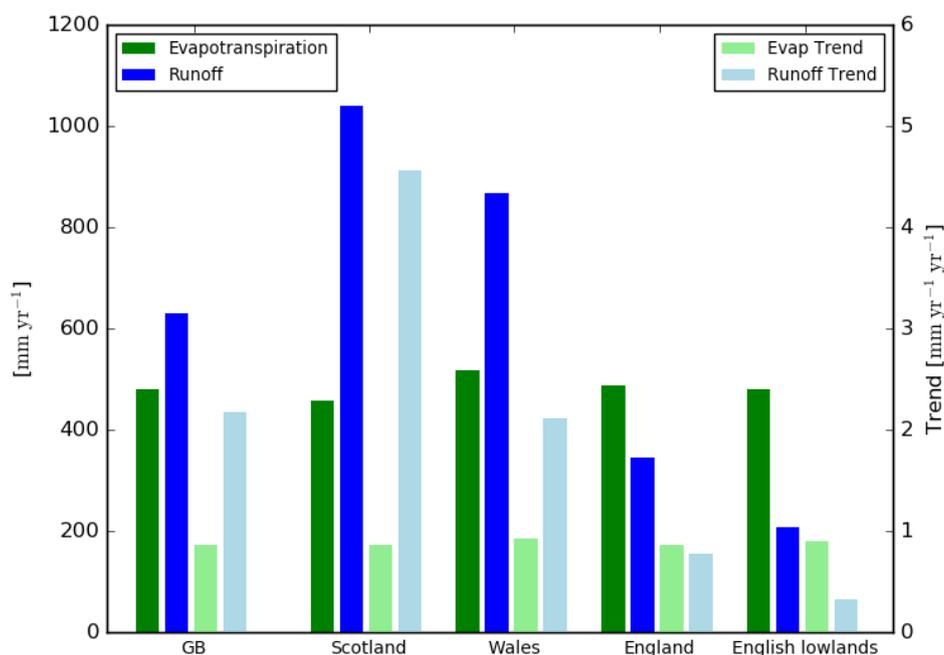

- 1 largest increase in the PET for GB was in spring due to an increase of spring sunshine hours and a
- 2 decrease in relative humidity. In Sect. 4 we discuss the impact of this on the riverflow.
- 3 Unlike the PET results however, the smallest trend of evapotranspiration is seen in the autumn. This
- 4 may be due to soil moisture control of evapotranspiration.
- 5 The trends in runoff are overall two times larger than the evapotranspiration trends. This is due to
- 6 the very large increase in winter runoff due to the large positive trend in precipitation in Scotland.
- 7 The other seasons have a similar upward trend of about $1 \text{ mm yr}^{-1} \text{ yr}^{-1}$.
- 8 3.2 Regional trends.

Annual Average (rate of change in units yr^{-1})	Scotland	Wales	England	English lowlands
Precipitation (mm yr^{-1})	1495 (5.41±3.00)	1386 (2.93±2.86)	832 (1.51±1.87)	686 (1.07±1.76)
Evapotranspiration (mm yr^{-1})	460 (0.87±0.47)	518 (0.93±0.72)	487 (0.86±0.66)	481 (0.91±0.71)
Runoff (mm yr^{-1})	1042 (4.56±2.82)	869 (2.12±2.80)	347 (0.79±1.75)	209 (0.33±1.50)
PET (mm yr^{-1})	423 (0.53±0.46)	496 (0.69±0.68)	509 (0.87±0.77)	519 (1.03±0.86)
Soil Moisture ($\text{m}^3 \text{ m}^{-3}$)	1534 (0.29±0.56)	1139 (- 0.03±0.66)	1128 (- 0.20±1.00)	1177 (- 0.29±1.12)
Observed total runoff (mm yr^{-1})	972 (3.60±2.63)	945 (2.67±3.72)	369 (0.38±1.83)	273 (0.13±1.68)

- 9 Table 6: Annual average GB and regional fluxes and trends in the fluxes of: Precipitation,
- 10 Evapotranspiration, Runoff, Potential Evapotranspiration and Soil Moisture. Bottom row shows
- 11 annual observed averages from NRFA runoff product.

12

1

2 Figure 13: Bar chart showing annual GB and regional water budgets and trends (evapotranspiration
 3 and runoff). Trends are represented on the right y-axis.

4 The water balance of the different regions can be summarised as follows: the water balance is runoff
 5 dominated in Scotland (runoff is 70% of rainfall) and evaporation dominated in the English lowlands
 6 (runoff is 30% of rainfall).

7 Table 6 and Fig. 13 show that the trend in evapotranspiration is roughly constant between regions,
 8 in the same way that the total evapotranspiration is fairly constant. However, the runoff trends are
 9 more varied between regions. Scotland dominates the trend with an increase in runoff of 4.56
 10 $\text{yr}^{-1} \text{yr}^{-1}$ and the English lowlands have the smallest trend of $0.33 \text{ mm yr}^{-1} \text{yr}^{-1}$.

11 3.3 Totals and trends in the components of evapotranspiration for GB.

12 There are three components of the evapotranspiration. The JULES model calculates each explicitly
 13 and their totals and trends for GB are given in Table 7.

	Average (mm yr^{-1})	Rate Of Change ($\text{mm yr}^{-1} \text{yr}^{-1}$)
Evapotranspiration	481	0.87 ± 0.55

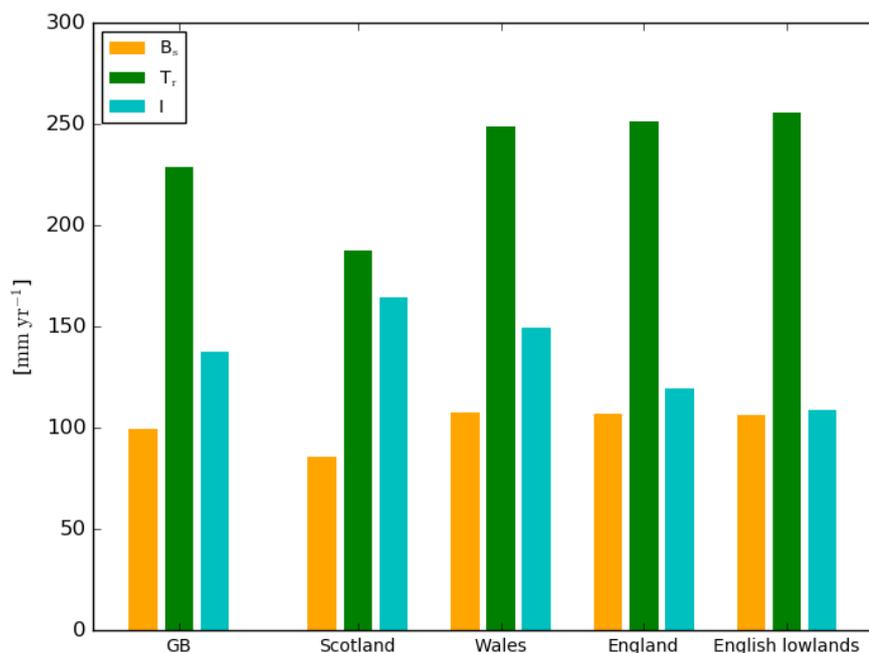

Soil surface evaporation	100 (21%)	0.14±0.47 (16%)
Transpiration	229 (48%)	0.47±0.23 (51%)
Interception	137 (28%)	0.31±0.22 (33%)

1 Table 7: Annual average and trends in GB evapotranspiration and components.

2 The percentage of evapotranspiration that is due to interception is about 30%, due to soil surface
3 evaporation is about 20% and due to transpiration is due to about 50%. Despite the possible errors
4 in the modelled allocation of evapotranspiration between the components reported in Sect. 2, it is
5 likely that the trends of the components are well represented. A key factor is the contribution of the
6 component to the trend in total evapotranspiration. These vary between components and they are
7 slightly different to the contributions they make to the annual average. This means they are not all
8 increasing at the same rate: the interception is increasing more rapidly than the other two
9 components. This is discussed in more detail in Sect. 4.

10 Figure 14 displays how the components vary across the regions. Although transpiration generally
11 dominates, they are nearly equal in Scotland which experiences very high rainfall rates.

12

13 Figure 14: Bar chart of annual average evapotranspiration components in GB and regions.

14

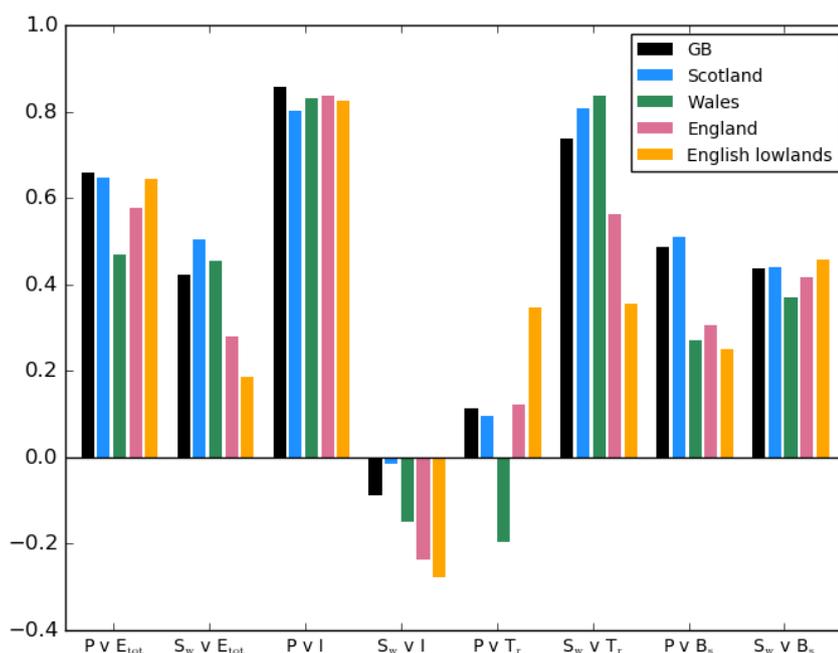

1 3.4 What meteorological variable is driving the trend?

2 To understand the reason for the trend in evapotranspiration, we study the correlation between the
 3 annual evapotranspiration and its two main drivers: precipitation and radiation. The analysis is
 4 carried out for the regions and for the separate components. A discussion of the trends in radiation
 5 due to changes in aerosols and cloud cover and how it is represented in the CHES dataset is given in
 6 Sect. 4.

7 Table 8 and Fig. 14 show the results of the correlations.

R	P v E_{tot}	S_w v E_{tot}	P v I	S_w v I	P v T_r	S_w v T_r	P v B_s	S_w v B_s
GB	0.66	0.42	0.86	-0.09	0.11	0.74	0.49	0.44
Scotland	0.65	0.50	0.80	-0.01	0.09	0.81	0.51	0.44
Wales	0.47	0.45	0.83	-0.15	-0.20	0.84	0.27	0.37
England	0.58	0.28	0.84	-0.24	0.12	0.56	0.31	0.42
English lowlands	0.64	0.19	0.82	-0.28	0.35	0.36	0.25	0.46

8 Table 8: Correlation of annual Precipitation (P) and Shortwave radiation (S_w) with Total
 9 evapotranspiration (E_{tot}), Interception (I), Transpiration (T_r) and Soil surface evaporation (B_s), for GB
 10 and for the four regions.

- 1 Figure 15: Bar chart showing correlation of annual Precipitation (P) and Shortwave radiation (S_w)
- 2 with Total evapotranspiration (E_{tot}), Interception (I), Transpiration (T_r) and Soil surface evaporation
- 3 (B_s) for GB and the regions.

- 4 The important take-away result from this Fig. 15 and Table 8 is that there is always a strong
- 5 correlation between rainfall and interception (3rd column in Fig 15 and Table 8) and always a strong
- 6 correlation of transpiration with radiation (6th column in Fig. 15 and Table 8).

- 7 From the analysis, soil surface evaporation seems to have similar correlations with both precipitation
- 8 and radiation.

- 9 The implications for these results is discussed in the following section.

1 4. Discussion

2 4.1 Trends in the annual GB water budget

3 Hannaford (2015) suggest that the overall runoff of GB is increasing by $1.6 \text{ mm yr}^{-1} \text{ yr}^{-1}$ while
4 Robinson et al (2017a) show an increase in precipitation of $2.86 \text{ mm yr}^{-1} \text{ yr}^{-1}$ (updated analysis of
5 data including later years shows $2.96 \text{ mm yr}^{-1} \text{ yr}^{-1}$ – Table 5) If this was taken as the only evidence for
6 a change in actual evapotranspiration, we could calculate an increase of $1.36 \text{ mm yr}^{-1} \text{ yr}^{-1}$. However,
7 Robinson et al (2017a) indicate an increase in PET, which represents an upper limit of transpiration,
8 of only $0.77 \text{ mm yr}^{-1} \text{ yr}^{-1}$ and Kay et al (2013) have suggested that the overall trend in
9 evapotranspiration of GB is close to the trend in PET, which they estimate as $0.7 \text{ mm yr}^{-1} \text{ yr}^{-1}$.

10 If all this were true, then there would be an increase in soil moisture or groundwater store of the
11 order of $0.5 \text{ mm yr}^{-1} \text{ yr}^{-1}$.

12 The results of this study give slightly different results. The overall trend in evapotranspiration is 0.87
13 $\text{mm yr}^{-1} \text{ yr}^{-1}$ and the runoff is larger than that given by Hannaford (2015) at $2.16 \text{ mm yr}^{-1} \text{ yr}^{-1}$. This
14 then almost balances the water budget leaving negligible increase in soil moisture or groundwater.

15 We have already demonstrated (Sect 2.2.4) that the Hannaford (2015) estimates of riverflow are too
16 low in Scotland. This was probably due to the use of large-scale area-average Potential Evaporation
17 over hilly terrain to gap-fill the data which will tend to overestimate the evaporative loss leading to
18 runoff-estimates that are too low. It is possible that the trend in runoff, rather than the total, is
19 affected by the lack of interception trend (discussed below) in the estimated runoff. A deeper
20 analysis of the flows in Scotland should be carried out to understand these trends.

21 The reason why the evaporative loss might be greater than the potential could be due to the large
22 fractional component of interception (30%): in the wet and windy areas (West Scotland), there is a
23 higher fraction of evergreen needle leaf trees which have a high interception capacity (see Calder,
24 1990). The evaporation from a wet forest often exceeds the PET, drawing down energy in the form
25 of negative sensible heat (i.e. cooling the air) to drive it (Stewart et al, 1977).

26 If the drivers of interception are increasing faster than the PET, then with such a high interception
27 fraction, there might be a larger trend in the evapotranspiration than the potential evaporation. This
28 is discussed in Sect. 4.4.

29 4.2 Impact of seasonal variation of trend in evapotranspiration on river flows.

1 The results of this study indicate a clear increasing trend in spring evapotranspiration, driven by an
2 increase in PET reported in Robinson et al (2017a).

3 It is interesting to note the impact of this on the river flows. In their review, Watts et al (2015)
4 suggest that there is no clear evidence of how actual evaporation has changed over the last few
5 decades. Hannaford (2015) notes that, while there is an observed increase in winter, summer and
6 autumn river flows from 1961 to 2010, there is a decrease in the spring (see table 1). This is
7 reiterated in Harrigan et al., (2017) who note that we need an ‘improved understanding of the
8 drivers of these seasonal changes in river flow’.

9 This study clearly indicates that some of the spring-time drop in runoff will be due increased
10 evapotranspiration in addition to a reduction of rainfall.

11 4.3 Temporal changes in shortwave radiation over the study time period in Great Britain.

12 There is an overall increase in downward short wave radiation apparent in the observations used in
13 this study of $1.1 \pm 0.7 \text{ Wm}^{-2} \text{ decade}^{-1}$ over GB.

14 There are two possible reasons for an increase in short wave radiation: one is that there is less cloud
15 and the other that the air is more transparent due to a reduction in aerosols (pollution).

16 The aerosol effect has been widely studied and is referred to as ‘dimming and brightening’ since, the
17 aerosol amount increased throughout the 20th century until about the 1970’s, when due to
18 legislation, it began to fall. Observations reported by Wild (2009) illustrate this at the global scale.
19 Across Europe, the dimming resulted in a decrease in the total Short Wave Radiation of 1.4 Wm^{-2}
20 decade^{-1} from the beginning of the century to the mid-1970s and the brightening to an increase of
21 $2.2 \text{ Wm}^{-2} \text{ decade}^{-1}$ up to the mid-1990s. This change in radiation has been shown to have a
22 significant impact on river flows in the region (Gedney et al 2014).

23 GB has a somewhat different temporal pattern of dimming and brightening to mainland Europe.
24 Using an ensemble of computer model runs, Folini and Wild (2011) simulated the aerosols in Europe.
25 Their results agree with the overall result of Wild (2009) for Europe, but also note some interesting
26 regional variations: in the case of GB from 1960 onward, there is no dimming, only brightening. For
27 the All-Sky conditions (i.e. including clouds. See Fig 9 of the Folini and Wild (2011) paper) the
28 increase in radiation is about $0.8 \text{ Wm}^{-2} \text{ decade}^{-1}$. This tallies with an observational study by Stjern et
29 al. (2009) which included a long term record at Aberdeen (the only GB station in the study) where
30 there was no dimming from 1960’s only a brightening of $1 \text{ Wm}^{-2} \text{ decade}^{-1}$. This is also consistent with
31 the increase of short wave ($0.9 \pm 1.1 \text{ Wm}^{-2} \text{ decade}^{-1}$ for the years 1979-2012) given in the

1 observation-based meteorological forcing dataset WFDEI (Weedon et al, 2014) which included
2 explicit aerosol effects.

3 The short-wave radiation data used in CHES is based on sun-shine hours. There is a spatially varying
4 aerosol effect included, but it is based on data from 1978 and does not change in time. As reported
5 in Robinson et al (2017), it may be that the aerosol effect is implicit in the sunshine hours record as
6 there is a threshold of 120 Wm^{-2} and the number of hours above that threshold will be affected by
7 the pollution levels, although the changes in cloud cover are likely to be dominant in this signal.

8 The biggest increase in short wave is in the spring. This is consistent with data from across Europe
9 (Sanchez-Lorenzo et al., 2008) and may be due to changes in the Atlantic Multidecadal Oscillation
10 (AMO) which has resulted in decreased spring precipitation in Northern Europe (Sutton and Dong,
11 2012).

12 It is concluded therefore that the CHES data gives a reasonable representation of the shortwave
13 radiation over GB for the study period.

14 4.4 Analysis of correlations.

15 It is generally accepted (e.g. Teuling et al., 2009, Wang and Dickenson, 2012), that in moisture
16 limited regions, there will be a strong correlation of evapotranspiration with precipitation, while in
17 wet, cloudy regions, there will be a stronger correlation with radiation. However, in the analysis
18 presented by Teuling et al (2009), most of GB is deemed to be radiation limited (confirming its wet
19 and cloudy climate) apart from west Scotland and central England. The result for west Scotland is a
20 counter-intuitive result since it is the wettest region of GB.

21 A correlation analysis of annual evapotranspiration with precipitation and short-wave radiation was
22 carried out with the CHES model results and reported in Sect. 3.4. In this analysis, the same
23 patterns emerged: the correlation of evapotranspiration and precipitation was high in Scotland. To
24 understand why the evapotranspiration correlates more strongly with precipitation than radiation in
25 Scotland, the correlations for the four regions for each of the components of evapotranspiration
26 against precipitation (P) and shortwave (S_w) radiation were made.

27 The important take-away result from this analysis (see Fig. 14 and Table 8) is that there is always a
28 strong correlation between rainfall and interception (3rd column in Fig 14 and Table 8). This tallies
29 with the results of the analysis in Sect. 4 and the evidence from Nisbet (2005) that interception is
30 near to a fixed fraction of rainfall. Interception is not 'limited' by rainfall, but it strongly correlates
31 with it because it is unlimited.

1 Transpiration however is generally limited by energy in GB since there is usually enough water and
2 often not enough sunshine. This results in a strong correlation of transpiration with radiation (6th
3 column in Fig. 14 and Table 8).

4 Soil surface evaporation has similar correlations with both precipitation and radiation.

5 These results show why the evapotranspiration-precipitation correlation dominates in Scotland: it is
6 because the rainfall is high and so interception is nearly as large as the Transpiration component of
7 the evapotranspiration (see Fig. 15). English lowlands provide the opposite case. The
8 evapotranspiration is dominated by transpiration (see Fig. 15) and it is equally water limited and
9 radiation limited.

10 4.5 Importance of interception to the GB hydrology.

11 As discussed above, this study highlights the importance of interception to the overall hydrological
12 balance and trends in GB. It may also have implications for floods.

13 Floods represent a major hazard for the UK and recently there has been effort to identify natural
14 ways to alleviate the floods. Dadson et al (2018) and Stratford et al (2017) both review the evidence
15 of whether the presence of trees have an impact to reduce flood peaks. They both conclude that
16 there can be an impact of mature trees to reduce smaller floods, probably do the interception.

17 Using a physically based model (JULES) with detailed representations of all the evaporation
18 components, including interception, enables us to quantify the effect of land-cover on hydrology at
19 the GB scale. The interception in the model has some uncertainties, and possibly underestimates the
20 effect (see Sect. 2.2.3). However, the results are consistent with the observations and can be used as
21 evidence for this increasingly important issue.

22 4.6 Possible impact of rising CO₂ levels on water balance of GB.

23 Over the 55 years of the study period, there has not only been a change in the physical climate, but a
24 50% increase in the atmospheric concentration of CO₂, from 300 ppm to 450 ppm. It is possible that
25 this has affected the water balance of GB due to the response of vegetation to CO₂. There is
26 evidence (Leakey et al, 2009) at the canopy scale that plants will transpire less in increased
27 atmospheric CO₂ levels. However, models differ substantially in their prediction of the large-scale,
28 long term response to elevated CO₂ which includes changes to ecosystems and vegetation structure
29 (de Kauwe et al, 2013).

1 The JULES model includes the effect of an increase in CO₂ on evapotranspiration, although it might
2 reduce the transpiration too much (Prudhomme et al, 2014). As a result of this uncertainty, in the
3 version of CHES reported here, we used the CO₂ level half way through the period (in 1986) and
4 kept it constant.

5 However, it is instructive to analyse to what extent the water balance would be predicted to change
6 in the presence of a 50% increase in CO₂ according to the model. The model showed that overall
7 evapotranspiration and runoff were unchanged. There was a change in the trend however:
8 evapotranspiration trend was reduced: to 0.60 mm yr⁻¹ yr⁻¹ (from 0.87 mm yr⁻¹ yr⁻¹) while the positive
9 trend in runoff increases: to 2.33 mm yr⁻¹ yr⁻¹ (from 2.16 mm yr⁻¹ yr⁻¹ with no CO₂ increase). Most of
10 the difference in trend comes from a lower positive trend in transpiration of 0.11 mm yr⁻¹ yr⁻¹
11 (compared to 0.47 mm yr⁻¹ yr⁻¹ in the constant CO₂ run). In the earlier part of the run, when transient
12 CO₂ levels were lower than the constant CO₂ run, the stomata were more open, so stomatal
13 conductance was higher, while the reverse was true in the later part of the run, with higher CO₂
14 levels. This leads to the same mean transpiration over the run, but a weaker trend.

15

1 5. Conclusions

2 This study set out to explore the long term evolution of the water budget of Great Britain (GB),
3 including how and why it is changing.

4 A study of the river flows (summarised in Hannaford, 2015) suggest that the runoff from GB is
5 increasing with time ($1.6 \text{ mm yr}^{-1} \text{ yr}^{-1}$ over the last 50 years) with a decrease in spring time (Harrigan
6 et al, 2017). It is possible that the increase is an underestimate due to the methods of gap-filing
7 used.

8 The Potential Evapotranspiration (PET), which expresses the likely increase of a well-watered grass
9 due to changes in wind, radiation and temperature, has been estimated by Robinson et al (2017a) to
10 be $0.77 \text{ mm yr}^{-1} \text{ yr}^{-1}$ and by Kay et al (2013) to be $0.7 \text{ mm yr}^{-1} \text{ yr}^{-1}$.

11 In order to examine the actual evapotranspiration, we used a validated model of the land surface
12 (JULES: Joint UK Land Environment Simulator) which was driven by observation-based
13 meteorological data (Robinson et al, 2017a) over 5 decades. The modelled evapotranspiration
14 increased at a rate of $0.87 \text{ mm yr}^{-1} \text{ yr}^{-1}$ which is greater than the increase in Potential
15 Evapotranspiration.

16 The analysis showed that the interception was a large component of the overall evapotranspiration
17 (30%) and increasing at a slightly higher rate (proportionally) than the other components.

18 In this paper, it was demonstrated that annual interception correlates strongly with annual
19 precipitation rather than solar radiation. Over the last 5 decades, precipitation has increased faster
20 ($2.96 \pm 2.03 \text{ mm yr}^{-1} \text{ yr}^{-1}$) than the PET ($0.74 \pm 0.66 \text{ mm yr}^{-1} \text{ yr}^{-1}$). This increase in precipitation,
21 combined with the high interception rates in GB (due to the wet conditions) explains why the trend
22 in evapotranspiration is higher than the trend in PET.

23 Thus the paper clearly demonstrated that a representation all three components of
24 evapotranspiration (interception, transpiration and bare-soil evaporation) are needed to understand
25 the trends in the GB water-budgets.

26 In addition, the study demonstrated the importance of evapotranspiration to the annual and
27 seasonal water budget of Great Britain and its regions. For instance, the observed decreasing spring-
28 time runoff reported in Harrigan et al (2017) is a combination of decreased in the precipitation and
29 increased evaporation in this season.

- 1 Future directions for this research should include a focus on the evaporation processes that have
- 2 been demonstrated to be so important: interception, the winter-time soil surface evaporation under
- 3 deciduous trees and the summer-time transpiration of grass. Narrowing our uncertainty in these key
- 4 processes will help identify the role of land cover on the UK water budgets.

1 6. Data and model availability

2 This paper presents the results of the model in a particular code version and configuration. The
3 version of a model refers to the code which are used to solve the equations of the processes (this
4 can be summarised by its Version Number). The configuration includes the selection of the options
5 used (such as whether to use dynamic vegetation or not), the look-up tables of parameters used in
6 the equations, the meteorological data used to drive the model and the ancillary data used to set up
7 the maps of soils and land cover classification. This will also have a Version Number and a reference
8 name. This information is given in Appendix B.

9 Code availability: The JULES code is available freely and can be applied for through the JULES
10 repository: <https://code.metoffice.gov.uk/trac/jules>. The version used for the CHESSE runs based
11 on JULES vn4.5, branch: r3488_albmar_spdm. More detailed information about the JULES code,
12 use and availability: <http://jules.jchmr.org>.

13 Data availability: The data (drivers and initial inputs) of the Configuration for running the model for
14 CHESSE is described in the rose suite number u-au394 (see Appendix B). All the model outputs
15 analysed here and more (evaporation components, runoff, latent and sensible fluxes, soil
16 moisture and temperature, surface temperature, carbon gross and net productivities) are
17 publicly available as the CEH CHESSE-land dataset (Martinez-de la Torre et al, 2018b).

18 The flux data used for evaluation is available upon request from the author.

19

1 Appendix A

2 A1 Overview of hydrology in JULES

3 This summary follows water as it arrives as precipitation at the land surface, and describes the
4 journey it takes through the land surface through interception, the snow pack, surface runoff
5 generation, vertical adjustment of soil moisture, drainage and evapotranspiration (Best et al, Clark et
6 al).

7 Each of the above-ground processes (interception, snow and evapotranspiration) are calculated for
8 each of the different land-surfaces represented within each grid-box. While the equations are
9 universal, the parameters change for each land cover type. The derivation of the maps of fractional
10 cover of each land cover and the parameters used are described in Appendix B.

11 The below ground processes (surface runoff generation, vertical adjustment of soil moisture and
12 drainage) are calculated based on the grid-average soil moisture. Parameters for these equations
13 depend on the soil type and topographical information. The derivation of these for CHES are given
14 in Appendix B.

15 Since this application is in the UK which has a temperate climate, we have not covered the cold
16 processes included in JULES, such as snow and soil freezing. Snow sublimation only accounts for 1%
17 of the modelled total evapotranspiration for the GB area (2% in Scotland, 0.5% in the rest of GB) and
18 so, for the sake of brevity, we have omitted to describe the snow model here. Readers are referred
19 to Best et al (2011) for more details.

20 A2. Rainfall intensity and interception

21 One of the most important aspects of any distributed hydrology model is how to deal with
22 precipitation that is supplied as a time- and space- average. If the precipitation is assumed to fall
23 evenly over a wide area or over a long time period, then infiltration through the vegetation canopy
24 or top soil layers is too low, resulting in a surface that is too wet and deeper soils that are too dry.

25 In JULES, the spatial distribution of intensity of rainfall is assumed to follow an exponential statistical
26 distribution.

27
$$f(P) = \left(\frac{\mu}{P}\right) \exp\left(\frac{-\mu P_i}{P}\right) \quad (A1)$$

1 where P ($\text{kg m}^{-2} \text{s}^{-1}$) is the area-average rainfall rate, P_i ($\text{kg m}^{-2} \text{s}^{-1}$) is the rainfall rate over a small area
 2 and μ is the fraction of the grid box area over which the rain is assumed to fall. In CHES, since the
 3 grid box is small, this is set as 1.

4 This rainfall-intensity distribution is used in two ways. Firstly to calculate how much of the rainfall
 5 falls through the vegetation canopy to the understorey, called ‘throughfall’ (T_f). Secondly, how much
 6 of the throughfall infiltrates the soil (see Sect. A3). The throughfall is dependent not just on the
 7 rainfall intensity but how much water is already on the leaves and also has a dripping element to it.

$$8 \quad T_f = P \left(1 - \frac{C}{C_m} \right) \exp \left(-\frac{\varepsilon C_m}{P \Delta t} \right) + P \frac{C}{C_m} \quad (\text{A2})$$

9 where C (mm) is the amount of rainfall stored on the leaves, C_m (mm) is the maximum capacity
 10 which depends on the leaf area index of the vegetation and ε is a tuning factor.

11 Vegetation is assumed to have a certain capacity that gets filled up by rain and reduced by
 12 evaporation, called ‘interception’. The interception rate is calculated as a fraction of the open-water
 13 evaporation rate, where the fraction (F) is the proportion of water stored to the maximum capacity
 14 of that vegetation type.

$$15 \quad F = \frac{C}{C_m} \quad (\text{A3})$$

16 The value of F (dimensionless) is converted to an effective surface resistance which is merged with
 17 resistances from the other evaporation components for the calculation of the tile-
 18 evapotranspiration based on the surface energy balance (see Sect. A6).

19 A3. Surface water partitioning

20 Surface runoff is generated either through infiltration excess (also known as Hortonian flow), or
 21 saturation excess (also known as Dunn flow). These are both represented in the JULES model.

22 Infiltration excess runoff will be generated by JULES if the water-flux over the time step (either
 23 rainfall, throughfall or snow melt) exceeds the maximum infiltration rate of the soil. The water-flux
 24 rate is assumed to vary in intensity across the grid and to have been altered by the interception (see
 25 Eq. (48) in Best et al, 2011). The maximum infiltration rate is the saturated hydraulic conductivity
 26 multiplied by a vegetation dependent parameter (4 for trees and 2 for grasses). However, this
 27 maximum infiltration rate is so high that it is never invoked.

28 Saturation excess runoff is based on the concept of the fact that the soil moisture across an area will
 29 not be uniform but that a fraction of the model grid cell (f_{sat}) will be at saturation. This fraction is

- 1 used as a multiplier on the remaining water arriving at the soil surface to convert to surface runoff.
 2 There are two options for representing this in JULES. In this study we use the PDM, based on a
 3 Pareto distribution to describe the spatial variation of soil moisture:

$$4 \quad f_{sat} = 1 - \left(1 - \frac{\theta - \theta_0}{\theta_s - \theta_0}\right)^{b/b-1} \quad (A4)$$

- 5 where θ ($\text{m}^3 \text{m}^{-3}$) is the mean volumetric soil moisture, θ_0 ($\text{m}^3 \text{m}^{-3}$) is the minimum soil moisture for
 6 the PDM scheme to start producing surface runoff, and θ_s ($\text{m}^3 \text{m}^{-3}$) the saturated soil moisture. b
 7 (dimensionless) is a tunable parameter. Martinez-de la Torre et al (2018a) introduced a method for
 8 identifying values of b and θ_0 from topographical data in the UK and these values are used here.

9 A4. Vertical soil water distribution

- 10 After the interception and the surface runoff, the remaining water enters the soil at the surface and
 11 is redistributed through the 3 m of soil moisture using the Darcy-Richard Equations. The resulting
 12 soil moisture profile allows the model to distinguish between the soil moisture near the surface
 13 which controls the soil surface evaporation and deeper layers which can be accessed by plants with
 14 different root depths (see Sect. A6). This distinction affects the sub-diurnal timing of energy fluxes
 15 which is important for weather prediction. The essential equations are as follows:

$$16 \quad W = k \left(\frac{d\psi}{dz} + 1 \right) \quad (A5)$$

- 17 where W ($\text{kg m}^{-2} \text{s}^{-1}$) is the vertical flux of water through the soil, z (m) is the vertical distance, k (kg
 18 $\text{m}^{-2} \text{s}^{-1}$) is the conductivity of the soil, and ψ is the suction (m). There are two options for calculating
 19 the conductivity and suction in JULES. In this study we use the van Genuchten (1980) formulations:

$$20 \quad \left(\frac{\theta}{\theta_s} \right) = \frac{1}{\left[1 + (\alpha\psi)^{\frac{1}{1-m}} \right]^m} \quad (A6)$$

$$21 \quad k = k_s \left(\frac{\theta}{\theta_s} \right)^{0.5} \left[1 - \left(1 - \left(\frac{\theta}{\theta_s} \right)^{1/m} \right)^m \right]^2 \quad (A7)$$

- 22 Where ψ_s (m) is the suction at saturation and k_s ($\text{kg m}^{-2} \text{s}^{-1}$) is the conductivity at saturation while α
 23 and m are model parameters. All four of these parameters are dependent on the soil type and the
 24 values used in CHES are described in Appendix B.

- 25 Not shown here are the heat-diffusion equations which act on the same layers. The transfer of heat
 26 is important to the soil hydrology when the soil freezes which alters the hydraulic conductivity.

1 A5. Drainage

2 The bottom boundary condition of the soil column can affect the performance of the model. At 3 m
3 deep in the standard version, the model is assumed to drain at the rate of the gravity drainage using
4 the soil moisture of the bottom layer – thus assuming there is an infinitely thick layer below with the
5 same soil moisture. Different options are available such as a zero flux layer or a deeper groundwater
6 store that can bring water upwelling and are presented in Best et al (2011).

7 A6. Evapotranspiration

8 Apart from the interception (see Sect. A1), the evaporation is assumed to consist of two
9 components: bare soil evaporation and transpiration.

10 The soil surface evaporation control is the simplest and depends on the soil moisture in the top
11 layer:

12
$$r_{soil} = 100 \left(\frac{\theta_c}{\theta_1} \right)^2 \quad (A8)$$

13 Where r_{soil} ($s\ m^{-1}$) is the surface resistance used for bare soil, θ_1 ($m^3\ m^{-3}$) is the soil moisture in the top
14 soil layer and θ_c ($m^3\ m^{-3}$) is the soil moisture at critical point (defined in Appendix B).

15 The transpiration is more complex as it depends on the response of the photosynthesis of the plant
16 to environmental controls: light levels, temperature, ambient carbon dioxide, soil moisture and
17 humidity. The surface resistance of the plant to the optimum photosynthesis (no limits) is inferred
18 and assumed to apply to the transpiration.

19 The effective surface resistance is made from a combination of the three components: interception,
20 bare soil and transpiration. The actual evapotranspiration depends on the amount of energy
21 available, which depends on the radiation balance and the soil heat fluxes. Details are given in Best
22 et al (2011).

23

1 Appendix B

2 The configuration (ancillary files, science options and parameters, and driving data) used for the
3 CHES simulation presented here are all documented in the rose suite u-au394
4 (<https://code.metoffice.gov.uk/trac/roses-u/browser/a/u/3/9/4/>). Instructions for how to access
5 this are given in the website: <http://jules.jchmr.org>. A summary of the options and driver datasets is
6 given here.

7 The model is run with 8 surface tiles (5 plant functional types: broadleaf trees, needleleaf trees,
8 grasses, shrubs and crops; and 3 non-vegetated types: open water, bare soil and urban) derived
9 from the CEH Land Cover 2000 (Fuller et al, 2002) map at a resolution of 25 m. Table B1 shows how
10 the Land Cover 2000 classes were mapped onto JULES land cover types. These were then aggregated
11 to 1 km resolution, as fractions of the total gridbox.

12 The soil hydrology component of JULES is based on the Darcy Richards equations (see Appendix A for
13 a summary) and, in this configuration, the van Genuchten (1980) approach, with the vertical
14 discretization into four layers of varying depth: 0.0-0.1 m, 0.1-0.35 m, 0.35-1.0 m and 1.0-3.0 m. The
15 soil hydraulic characteristics are assumed to be spatially uniform for each grid cell, and have been
16 calculated for the model domain from the Harmonised World Soil Database (HWSD;
17 FAO/IIASA/ISRIC/ISS-CAS/JRC, 2012), by classifying soils by their texture, then using the values from
18 Wösten et al (1999). We used a newly developed terrain slope dependency for the PDM scheme in
19 the production of saturation excess runoff (Martinez-de la Torre et al, 2018a), and the slope was
20 derived from the Great Britain 50 m resolution CEH-IHDTM database (Morris and Flavin, 1990;
21 1994).

22 The phenology for each month was prescribed for the deciduous vegetation and the crops. The
23 dynamical vegetation scheme was switched off. A 10-layer approach is used for canopy radiation
24 interception, including an exponential decline of leaf nitrogen with canopy height. For the run with
25 increasing atmospheric CO₂ concentration, we used annual values from the US NOAA (National
26 Oceanic and Atmospheric Administration) Global Monitoring Division
27 (<https://www.esrl.noaa.gov/gmd/ccgg/trends/global.html>).

28 A 10-year spin up run was conducted to initialize the model. The meteorological data used to drive
29 the model is publicly available (CHES-met: Robinson et al, 2017b). It is a daily dataset based on
30 observations from 1961 to 2015. The model is integrated at a half-hourly time step, using a daily
31 disaggregation scheme (Williams and Clark, 2014) to disaggregate the driving data. In terms of
32 precipitation, precipitation events start at a random time during the day and last for 2 hours in the

1 case of convective precipitation, or 5 hours in the case of large-scale precipitation. The input rainfall
2 is assumed to be convective for temperatures above 15 °C, and covers the complete 1 km grid
3 cell. The rest of options and parameters (radiation, snow, vegetation, non-vegetated tiles) are
4 available on the rose suite u-au394.

5

6

7

Land Cover 2000 class	JULES surface type
Water (inland)	Water
Saltmarsh	Water
Supra-littoral rock	Bare soil
Supra-littoral sediment	Bare soil
Bog (deep peat)	Shrub
Dense dwarf shrub heath	Shrub
Open dwarf shrub heath	Shrub
Montane habitats	Shrub
Broad-leaved / mixed woodland	Broadleaf tree
Coniferous woodland	Needleleaf tree
Improved grassland	Grass
Neutral grass	Grass
Setaside grass	Grass
Bracken	Shrub
Calcareous grass	Grass
Acid grassland	Grass
Fen, marsh, swamp	Grass
Arable cereals	Crop

Arable horticulture	Crop
Arable non-rotational	Shrub
Suburban / rural development	Urban
Continuous urban	Urban
Inland bare ground	Bare soil

1 Table B1 Allocation of Land Cover 2000 map classes to JULES surface types

2 Author Contribution: EMB designed the study, carried out the analysis and wrote the manuscript,
3 AM performed the model runs, summarised the results and created the figures, ELR set up the
4 system for running the model (ancillary data and driving data) and for evaluating the model with the
5 flux data and runoff data.
