17 **Abstract**

18 River systems that support high biodiversity profiles are conservation priorities world-wide.
19 Understanding river eco-system thresholds to low flow conditions is important for the
20 conservation of these systems. While climatic variations are likely to impact the streamflow
21 variability of many river courses into the future, understanding specific river flow dynamics
22 with regard to streamflow variability and aquifer baseflow contributions are central to the
23 implementation of protection strategies. While streamflow is a measurable quantity, baseflow
24 has to be estimated or calculated through the incorporation of hydrogeological variables. In

25 this study, the groundwater components within the J2000 rainfall/runoff model were distributed
26 to provide daily baseflow and streamflow estimates needed for reserve determination. The
27 modelling approach was applied to the RAMSAR-listed Verlorenvlei estuarine lake system on
28 the west coast of South Africa which is under threat due to agricultural expansion and climatic
29 fluctuations. The sub-catchment consists of four main tributaries, Krom Antonies, Hol,
30 Bergvallei and Kruismans. Of these, Krom Antonies was initially presumed the largest
31 baseflow contributor, but was shown to have significant streamflow variability, attributed to
32 the highly conductive nature of the Table Mountain Group sandstones and quaternary
33 sediments. Instead, Bergvallei was identified as the major contributor of baseflow. Hol was the
34 least susceptible to streamflow fluctuations due to the higher baseflow proportion (56 %), as
35 well as the dominance of less conductive Malmesbury shales that underlie it. The estimated
36 flow exceedance probabilities indicated that during the 2008-2017 wet cycle average lake
37 inflows exceeded the average evaporation demand, although yearly rainfall is twice as variable
38 in comparison to the first wet cycle between 1987-1996. During the 1997-2007 dry cycle,
39 average lake inflows are exceeded 85 % of the time by the evaporation demand. The
40 exceedance probabilities estimated here suggest that inflows from the four main tributaries are
41 not enough to support Verlorenvlei, with the evaporation demand of the entire lake being met
42 only 35 % of the time. This highlights the importance of low occurrence events for filling up
43 Verlorenvlei, allowing for regeneration of lake-supported ecosystems. As climate change
44 drives increased temperatures and rainfall variability, the length of dry cycles is likely to
45 increase into the future and result in the lake drying up more frequently. For this reason, it is
46 important to ensure that water resources are not overallocated during wet cycles, hindering
47 ecosystem regeneration and prolonging the length of these dry cycle conditions.

48 **1. Introduction**

49 Functioning river systems offer numerous economic and social benefits to society including
50 water supply, nutrient cycling and disturbance regulation amongst others (Costanza et al., 1997;
51 Nelson et al., 2009; Postel and Carpenter, 1997). As a result, many countries worldwide have
52 endeavoured to protect river ecosystems, although only after provision has been made for basic
53 human needs (Gleick, 2003; Richter et al., 2012; Ridoutt and Pfister, 2010). However, the
54 implementation of river protection has been problematic, because many river courses and flow
55 regimes have been severely altered due to socio-economic development (Gleeson and Richter,
56 2018; O’Keeffe, 2009; Richter, 2010). River health problems were thought to only result from
57 low-flow conditions and if minimum flows were kept above a critical level, the river’s
58 ecosystem would be protected (Poff et al., 1997; Tennant, 1976). It is now recognised that a
59 more natural flow regime, which includes floods as well as low and medium flow conditions,
60 is required for sufficient ecosystem functioning (Arthington et al., 2018; Bunn and Arthington,
61 2002; Olden and Naiman, 2010; Postel and Richter, 2012). For these reasons, before protection
62 strategies can be developed or implemented for a river system, a comprehensive understanding
63 of the river flow regime dynamics is necessary.

64 River flow regime dynamics include consideration of not just the surface water in the river but
65 also other water contributions including runoff, interflow and baseflow which are all essential
66 for the maintenance of the discharge requirements. Taken together these factors all contribute
67 to the hydrological components of what is called the ecological reserve, the minimum
68 environmental conditions needed to maintain the ecological health of a river system (Hughes,
69 2001; King and Louw, 1998; Richter et al., 2003). A variety of different methods have been
70 developed to incorporate various river health factors into ecological reserve determination
71 (Acreman and Dunbar, 2004; Bragg et al., 2005). One of the simplest and most widely applied,
72 is where compensation flows are set below reservoirs and weirs, using flow duration curves to

73 derive mean flow or flow exceedance probabilities (e.g. Harman and Stewardson, 2005). This
74 approach focusses purely on hydrological indices, which are rarely ecologically valid (e.g.
75 Barker and Kirmond, 1998; Lancaster and Downes, 2010).

76 More comprehensive ecological reserve estimates such as functional analysis are focused on
77 the whole ecosystem, including both hydraulic and ecological data (e.g. ELOHA: Poff et al.,
78 2010; Building Block Methodology: King and Louw, 1998). While these methods consider that
79 a variety of low, medium and high flow events are important for maintaining ecosystem
80 diversity, they require specific data regarding the hydrology and ecology of a river system,
81 which in many cases does not exist, has not been recorded continuously or for sufficient
82 duration (Acreman and Dunbar, 2004; Richter et al., 2012). To speed up ecological reserve
83 determination, river flow records have been used to analyse natural seasonality and variability
84 of flows (e.g. Hughes and Hannart, 2003). However, this approach requires long-term
85 streamflow and baseflow timeseries. Whilst streamflow is a measurable quantity subject to a
86 gauging station being in place, baseflow has to be modelled based on hydrological and
87 hydrogeological variables.

88 Rainfall/runoff models can be used to calculate hydrological variables using distributive
89 surface water components (e.g. J2000: Krause, 2001; SWAT: Arnold et al., 1998) but the
90 groundwater components are generally lumped within conventional modelling frameworks. In
91 contrast, groundwater models, which distribute groundwater variables (e.g. MODFLOW:
92 Harbaugh et al., 2000; FEFLOW: Diersch, 2002) are frequently set up to lump climate
93 components. In order to accurately model daily baseflow, which is needed for reserve
94 determination, modelling systems need to be setup such that both groundwater and climate
95 variables are treated in a distributed manner (e.g. Bauer et al., 2006; Kim et al., 2008).
96 Rainfall/runoff models, which use Hydrological Response Units (HRUs) as an entity of
97 homogenous climate, rainfall, soil and landuse properties (Flügel, 1995; Leavesley and

98 Stannard, 1990), are able to reproduce hydrographs through model calibration (Wagener and
99 Wheater, 2006; Young, 2006). However, they are rarely able to correctly proportion runoff and
100 baseflow components (e.g. Willems, 2009; Hughes, 2004). To correctly determine
101 groundwater baseflow using rainfall/runoff models such as the J2000, aquifer components need
102 to be distributed. This can be achieved using net recharge and hydraulic conductivity collected
103 through aquifer testing or groundwater modelling.

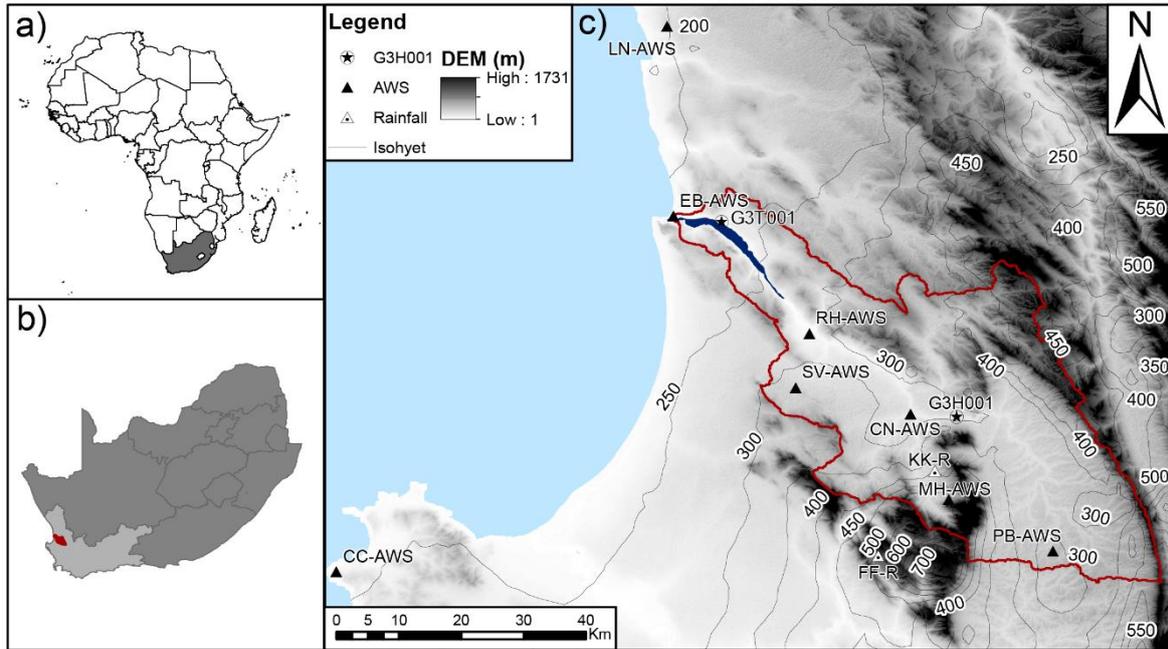

104 To better understand river flow variability, a rainfall/runoff model was distributed to
105 incorporate aquifer hydraulic conductivity within model HRUs using calibrated values from a
106 MODFLOW groundwater model (Watson, 2018). The model was setup for the RAMSAR
107 listed Verlorenvlei estuarine lake on the west coast of South Africa, which is under threat from
108 climate change, agricultural expansion and mining exploration. The rainfall/runoff model used
109 was J2000 as this model had previously been set up in the region and model variables were
110 well established (e.g Bagan, 2014; Schulz et al., 2013). While the estuarine lake's importance
111 is well documented (Martens et al., 1996; Wishart, 2000), the lake's reserve is not well
112 understood, due to the lack of streamflow and baseflow estimates for the main feeding
113 tributaries of the system. The modelling framework developed in this study aimed to
114 understand the flow variability of the lake's feeding tributaries, to provide the hydrological
115 components (baseflow and runoff proportioning) of the tributaries needed to understand the
116 lake reserve. The surface water and groundwater components of the model were calibrated for
117 two different tributaries which were believed to be the main source of runoff and baseflow for
118 the sub-catchment. The baseflow and runoff rates calculated from the model indicate not only
119 that the lake system cannot be sustained by baseflow during low flow periods but also that the
120 initial understanding of which tributaries are key to the sustainability of the lake system was
121 not correct. The results have important implications for how we understand water dynamics in

122 water stressed catchments and the sustainability of ecological systems in these types of
123 environments generally.

124 **2. Study site**

125 Verlorenvlei is an estuarine lake situated on the west coast of South Africa, approximately 150
126 km north of the metropolitan city of Cape Town (Fig. 1). The west coast, which is situated in
127 the Western Cape Province of South Africa, is subject to a Mediterranean climate where the
128 majority of rainfall is received between May to September. The Verlorenvlei lake, which is
129 approximately 15 km² in size draining a watershed of 1832 km², forms the southern sub-
130 catchment of the Olifants/Doorn water management area (WMA). The lake hosts both Karroid
131 and Fynbos biomes, with a variety of vegetation types (e.g Arid Estuarine Saltmarsh, Cape
132 Inland Salt pans) sensitive to reduced inflows of freshwater (Helme, 2007). A sandbar created
133 around a sandstone outcrop (Table Mountain Group; TMG) allows for an intermittent
134 connection between salt and fresh water. During storms or extremely high tides, water scours
135 the sand bar allowing for a tidal exchange, with a constant inflow of salt water continuing until
136 the inflow velocity decreases enough for a new sand bar to form (Sinclair et al., 1986).

137 The lake is supplied by four main tributaries which are Krom Antonies, Bergvallei, Hol and
138 Kruismans (Fig. 2). The main freshwater sources are presumed to be Krom Antonies and
139 Bergvallei, which drain the mountainous regions to the south (Piketberg) and north of the sub-
140 catchment respectfully. Hol and Kruismans tributaries are variably saline (Sigidi, 2018), due
141 to high evaporation rates in the valley. Average daily temperatures during summer within the
142 sub-catchment are between 20-30 °C, with estimated potential evaporation rates of 4 to 6 mm.d⁻¹
143 (Muche et al., 2018). In comparison, winter daily average temperatures are between 12-20 °C,
144 with estimated potential evaporation rates of 1 to 3 mm.d⁻¹ (Muche et al., 2018).

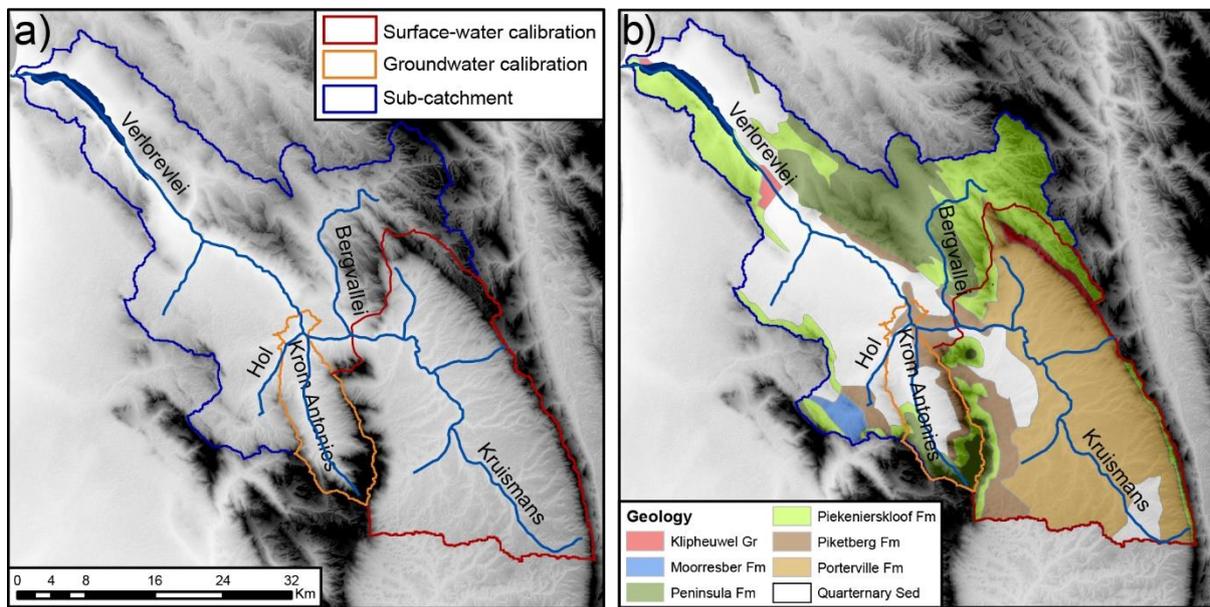

145

146 Figure 1: a) Location of South Africa, b) the location of the study catchment within the Western

147 Cape and c) the extend of the Verlorenvlei sub-catchment with the climate stations, gauging

148 station (G3H001), measured lake water level (G3T001) and rainfall isohyets

149

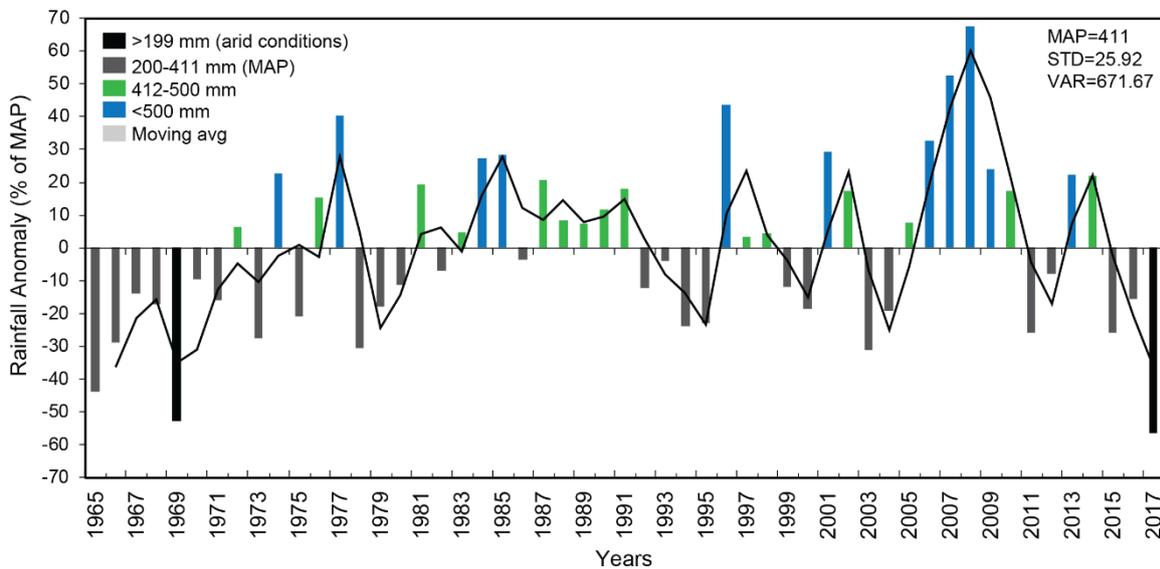

150 Figure 2: a) The Verlorenvlei sub-catchment with the surface water calibration tributary

151 (Kruismans) and groundwater calibration tributary (Krom Antonies) and b) the hydrogeology

152 of the sub-catchment with Malmesbury shale formations (MG; Klipheuwel, Mooresberg,

153 Porterville, Piketberg), Table Mountain Group formations (Peninsula, Piekenierskloof) and
154 quaternary sediments

155 Rainfall for the sub-catchment, recorded over the past 52 years by local farmers at KK-R (Fig.
156 1) shows large yearly variability (26 %) between the Mean Annual Precipitation (MAP) (411
157 mm) and measured rainfall (Fig. 3). Where rainfall was greater than 500 mm.yr⁻¹ (2006-2010),
158 it is presumed that the lake is supported by a constant influx of streamflow from the feeding
159 tributaries. Recently, where rainfall was less than 50 % of the MAP (2015-2017), concerns
160 over the amount of streamflow required to support the lake have been raised.

161
162 Figure 3: The difference between MAP and measured rainfall (plotted as rainfall anomaly) for
163 52 years (1965-2017) at location KK-R in the valley of Krom Antonies (after Watson *et al.*,
164 2018).

165 While rainfall varies greatly between years in the sub-catchment, it is also spatially impacted
166 by elevational differences. The catchment valley which receives the least MAP 100-350 mm.yr⁻¹
167 ¹ (Lynch, 2004), is between 0-350 masl and is comprised of quaternary sediments that vary in
168 texture, although the majority of the sediments in the sub-catchment are sandy in nature. The

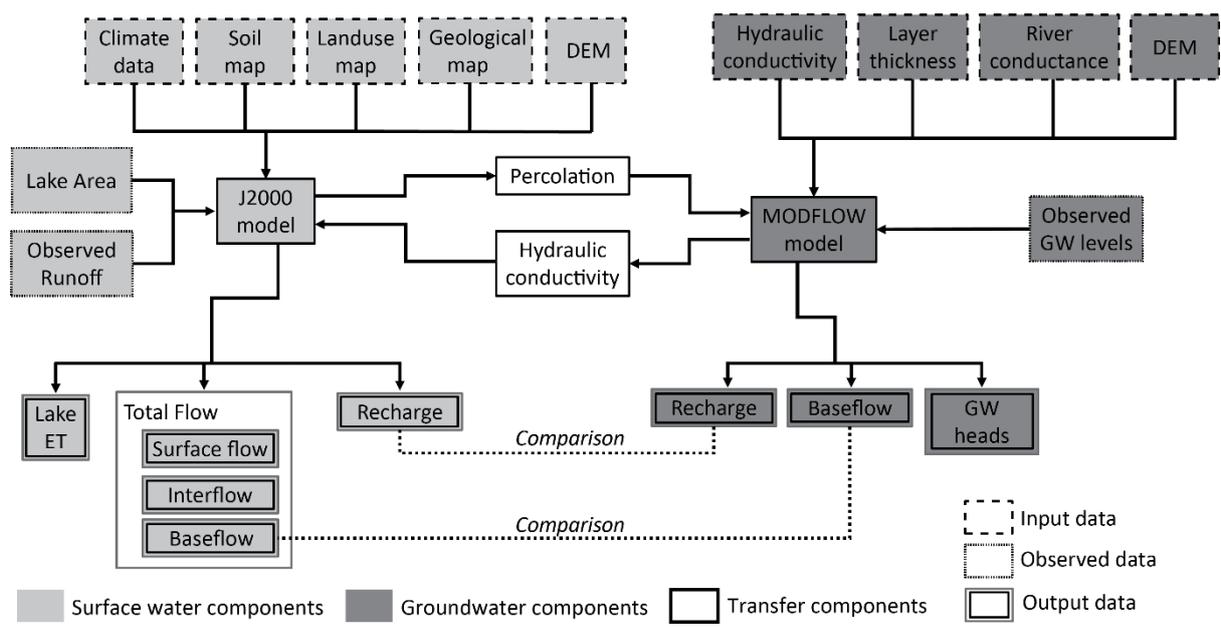

169 higher relief mountainous regions of the sub-catchment between 400-1300 masl receive the
170 highest MAP 400-800 mm.yr⁻¹ (Lynch, 2004), are mainly comprised of fractured TMG
171 sandstones, (youngest to oldest): Peninsula, Graafwater (not shown), and Piekernerskloof
172 formations (Fig. 2) (Johnson et al., 2006). Underlying the sandstones and quaternary sediments
173 are the MG shales, which are comprised of the Mooresberg, Piketberg and Klipheuwel
174 formations (Fig. 2) (Rozendaal and Gresse, 1994). Agriculture is the dominant water user in
175 the sub-catchment with an estimated usage of 20 % of the total recharge (Conrad et al., 2004;
176 DWAF, 2003), with the main food crop being potatoes. The MG shales and quaternary
177 sediments, which host the secondary and primary aquifer respectfully, are frequently used to
178 supplement irrigation during the summer months of the year. During winter, the majority of
179 the irrigation water needed for crop growth is supplied by the sub-catchment tributaries or the
180 lake itself. The impact of irrigation on the lake is still regarded as minimal (Meinhardt et al.,
181 2018) but further investigation is still required. For additional information regarding the study
182 site refer to Watson *et al.*, (2018) and Conrad *et al.*, (2004).

183 **3. Methodology**

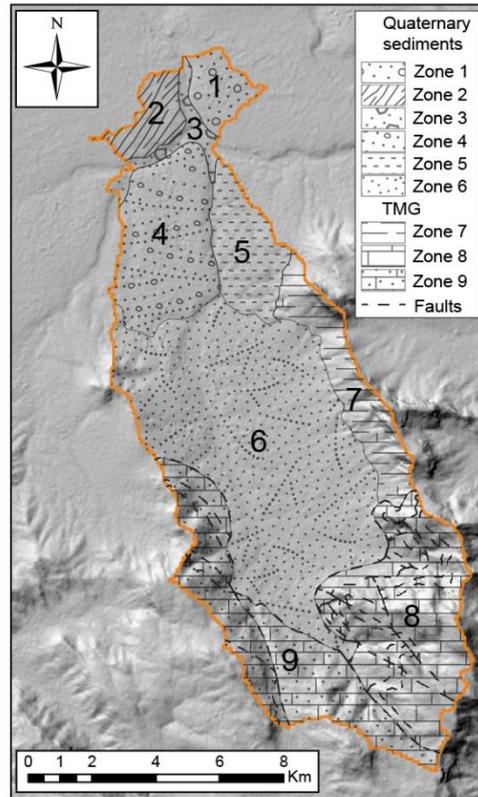

184 In this study, the J2000 coding was adapted to incorporate distributed groundwater components
185 for the model HRU's (Fig. 4). This was done by aligning the MODFLOW recharge estimates
186 and previous studies (Conrad et al., 2004; Miller et al., 2017; Vetger, 1995; Weaver and Talma,
187 2005; Wu, 2005) with those of the J2000, through adjustment of aquifer hydraulic conductivity
188 from the MODFLOW groundwater model of Krom Antonies (Watson, 2018) (Fig. 5). The
189 assigned hydraulic conductivity for each geological formation was thereafter transferred across
190 the entire J2000 model of the sub-catchment. The adaption applied to the groundwater
191 components influenced the proportioning of water routed to runoff and baseflow within the
192 J2000 model. To validate the outputs of the model, an empirical mode decomposition (EMD)

193 (Huang et al., 1998) was applied to compute the proportion of variation in discharge timeseries
 194 that attributed to a high and low water level change at the sub-catchment outlet. The streamflow
 195 estimates were thereafter compared with the lake evaporation demand, to understand the sub-
 196 catchment water balance.

197 The J2000 model incorporated distributed climate, soil, landuse and hydrogeological
 198 information, with aquifer hydraulic conductivity transferred from MODFLOW as described
 199 above (Fig. 4). The measured streamflow was used to both calibrate and validate the model,
 200 with the landuse dataset being selected according to the period of measured streamflow.
 201 Changes in the recorded lake level were used alongside remote sensing to estimate the lake
 202 evaporation rate. The impact of irrigation was not included in the model, as there is not enough
 203 information available regarding agricultural water use. This is currently one of the major
 204 limitations with the study approach presented here and will be the focus of future work. The
 205 HRU delineation, model regionalisation, water balance calculations, lateral and reach routing
 206 as well as the lake evaporation procedure are presented. Thereafter the input data for the model,
 207 the calibration and validation procedures as well as the EMD protocol used, is described.

209 Figure 4: Schematic of the model structure, showing the processors simulated by the J2000 and
210 MODFLOW and the components that were transferred from the MODFLOW model

211

212 Figure 5: The aquifer hydraulic zones used for the groundwater calibration of the J2000 (after
213 Watson, 2018)

214 3.1 Hydrological Response Unit Delineation

215 HRUs and stream segments (reaches) are used within the J2000 model for distributed
216 topographic and physiological modelling. In this study, the HRU delineation made use of a
217 digital elevation model, with slope, aspect, solar radiation index, mass balance index and
218 topographic wetness being derived. Before the delineation process, gaps within the digital
219 elevation model were filled using a standard fill algorithm from ArcInfo (Jenson and
220 Domingue, 1988). The AML (ArcMarkupLanguage) automated tool (Pfennig et al., 2009) was
221 used for the HRU delineation, with between 13 and 14 HRUs/km² being defined

222 (Pfannschmidt, 2008). After the delineation of HRUs, dominant soil, land use and geology
223 properties were assigned to each. The hydrological topology was defined for each HRU by
224 identifying the adjacent HRUs or stream segments that received water fluxes.

225 **3.2 Model regionalisation**

226 Rainfall and relative humidity are the two main parameters that are regionalised within the
227 J2000 model. While a direct regionalisation using an inverse-distance method (IDW) and the
228 elevation of each HRU can be applied to rainfall data, the regionalisation of relative humidity
229 requires the calculation of absolute humidity. The regionalisation of rainfall records was
230 applied by defining the number of weather station records available and estimating the
231 influence on the rainfall amount for each HRU. A weighting for each station using the distance
232 of each station to the area of interest was applied to each rainfall record, using an elevation
233 correction factor (Krause, 2001). The relative humidity and air temperature measured at set
234 weather stations was used to calculate the absolute humidity. Absolute humidity was thereafter
235 regionalised using the IDW method, station and HRU elevation. After the regionalisation had
236 been applied, the absolute humidity was converted back to relative humidity through
237 calculation of saturated vapor pressure and the maximum humidity.

238 **3.3 Water balance calculations**

239 The J2000 model is divided into calculations that impact surface water and groundwater
240 processors. The J2000 model distributes the regionalised precipitation (P) calculated for each
241 HRU using a water balance defined as:

$$P = R + Int_{max} + ETR + \Delta Soil_{sat} \quad (1)$$

242 where R is runoff (mm) (RD1 - surface runoff; RD2 - interflow), Int_{max} is vegetation canopy
243 interception (mm), ETR is 'real' evapotranspiration and $\Delta Soil_{sat}$ is change in soil saturation.
244 The surface water processes have an impact on the amount of modelled runoff and interflow,

245 while the groundwater processors influence the upper and lower groundwater flow
246 components.

247 **3.3.1 Surface water components**

248 Potential evaporation (ETP) within the J2000 model is calculated using the Penman Monteith
249 equation. Before evaporation was calculated for each HRU, interception was subtracted from
250 precipitation using the leaf area index and leaf storage capacity for vegetation (a_{rain})
251 (Supplementary: Table 1). Evaporation within the model considers several variables that
252 influence the overall modelled evaporation. Firstly, evaporation is influenced by a slope factor,
253 which was used to reduce ETP based on a linear function. Secondly, the model assumed that
254 vegetation transpires until a particular soil moisture content where ETP is reached, after which
255 modelled evaporation was reduced proportionally to the ETP, until it becomes zero at the
256 permanent wilting point.

257 The soil module in the J2000 model is divided up into processing and storage units. Processing
258 units in the soil module include soil-water infiltration and evapotranspiration, while storage
259 units include middle pore storage (MPS), large pore storage (LPS) and depression storage. The
260 infiltrated precipitation was calculated using the relative saturation of the soil, and its maximum
261 infiltration rate ($SoilMaxInfSummer$ and $SoilMaxInfWinter$) (Supplementary: Table 1).
262 Surface runoff was generated when the maximum infiltration threshold was exceeded. The
263 amount of water leaving LPS, which can contribute to recharge, was dependant on soil
264 saturation and the filling of LPS via infiltrated precipitation. Net recharge (R_{net}) was estimated
265 using the hydraulic conductivity ($SoilMaxPerc$), the outflow from LPS (LPS_{out}) and the slope
266 ($slope$) of the HRU according to:

$$R_{net} = LPS_{out} \times (1 - \tan (slope) SoilMaxPerc) \quad (2)$$

267 The hydraulic conductivity, *SoilMaxPerc* and the adjusted LPS_{out} were thereafter used to
 268 calculate interflow (IT_f) according to:

$$IT_f = LPS_{out} \times (\tan(\text{slope}) \text{SoilMaxPerc}) \quad (3)$$

269 with the interflow calculated representing the sub-surface runoff component RD2 and is routed
 270 as runoff within the model.

271 3.3.2 Groundwater components

272 The J2000 model for the Verlorenvlei sub-catchment was set up with two different geological
 273 reservoirs: (1) the primary aquifer (upper groundwater reservoir - RG1), which consists of
 274 quaternary sediments with a high permeability; and (2) the secondary aquifer (lower
 275 groundwater reservoir- RG2), made up of MG shales and TMG sandstones (Table 1).

Aquifer	Formation	Type	RG1_max (mm)	RG2_max (mm)	RG1_k (d)	RG2_k (d)	RG1_active (n/a)	Kf_geo (mm/d)	depthRG1 (cm)
Primary	Quaternary Sediments	Sediments	50	700	100	431	1	500	1750
Secondary/MG	Moorresberg Formation	Shale Greywacke	0	580	0	350	0	950	1750
Secondary/MG	Porterville Formation	Shale Greywacke	0	560	0	335	0	2	1750
Secondary/MG	Piketberg Formation	Shale Greywacke	0	1000	0	600	0	950	1750
Secondary/MG	Klipheuwel Group	Shale Greywacke	0	500	0	300	0	950	1750
Secondary/TMG	Peninsula Formation	Sandstone	0	1000	0	600	0	950	1750
Secondary/TMG	Piekenierskloof Formation	Sandstone	0	600	0	400	0	1	1750

276
 277 Table 1: The J2000 hydrogeological parameters RG1_max, RG2_max, RG1_k, RG2_Kf_geo
 278 and depthRG1 assigned to the primary and secondary aquifer formations for the Verlorenvlei
 279 sub-catchment

280 The model therefore considered two baseflow components, a fast one from RG1 and a slower
 281 one from RG2. The filling of the groundwater reservoirs was done by net recharge, with
 282 emptying of the reservoirs possible by lateral subterranean runoff as well as capillary action in
 283 the unsaturated zone. Each groundwater reservoir was parameterised separately using the
 284 maximum storage capacity (maxRG1 and maxRG2) and the retention coefficients for each
 285 reservoir ($recRG1$ and $recRG2$). The outflow from the reservoirs was determined as a function
 286 of the actual filling ($actRG1$ and $actRG2$) of the reservoirs and a linear drain function.

287 Calibration parameters $recRG1$ and $recRG2$ are storage residence time parameters. The
 288 outflow from each reservoir was defined as:

$$OutRG1 = \frac{1}{gwRG1Fact \times recRG1} \times actRG1 \quad (4)$$

$$OutRG2 = \frac{1}{gwRG2Fact \times recRG2} \times actRG2 \quad (5)$$

289 where $OutRG1$ is the outflow from the upper reservoir, $OutRG2$ is the outflow from the lower
 290 reservoir and $gwRG1Fact/ gwRG2Fact$ are calibration parameters for the upper and lower
 291 reservoir used to determine the outflow from each reservoir. To allocate the quantity of net
 292 recharge between the upper (RG1) and lower (RG2) groundwater reservoirs, a calibration
 293 coefficient $gwRG1RG2sdist$ was used to distribute the net recharge for each HRU using the
 294 HRU slope. The influx of groundwater into the shallow reservoir ($inRG1$) was defined as:

$$inRG1 = R_{net} \times (1 - (1 - \tan(slope))) \times gwRG1RG2sdist \quad (6)$$

295 The influx of net recharge into the lower groundwater reservoir ($inRG2$) was defined as:

$$inRG2 = R_{net} \times (1 - \tan(slope)) \times gwRG1RG2sdist \quad (7)$$

296 with the combination of $OutRG1$ and $OutRG2$ representing the baseflow component that is
 297 routed as an outflow from the model.

298 **3.4 Lateral and reach routing**

299 Lateral routing was responsible for water transfer within the model and included HRU influxes
 300 and discharge through routing of cascading HRUs from the upper catchment to the exit stream.
 301 HRUs were either able to drain into multiple receiving HRUs or into reach segments, where
 302 the topographic ID within the HRU dataset determined the drain order. The reach routing
 303 module was used to determine the flow within the channels of the river using the kinematic
 304 wave equation and calculations of flow according to Manning and Strickler. The river

305 discharge was determined using the roughness coefficient of the stream (Manning roughness),
306 the slope and width of the river channel and calculations of flow velocity and hydraulic radius
307 calculated during model simulations.

308 **3.5 Calculations of lake evaporation rate**

309 The lake evaporation rate was based on the ETP calculated by the J2000 and an estimated lake
310 surface area. The lake was modelled as a unique HRU (water as the land-cover type), with a
311 variable area which was estimated using remote sensing data from Landsat 8 and Sentinel-2
312 and the measured lake water level at G3T001 (Fig. 1). To infill lake surface area when remote
313 sensing data was not available, a relationship was created between the estimated lake's surface
314 area and the measured water level between 2015-2017. Where lake water level data was not
315 available (before 1999), an average long-term monthly value was used for the lake evaporation
316 calculations.

317 **3.6 J2000 Input data**

318 ***3.6.1 Surface water parameters***

319 Climate and rainfall: Rainfall, windspeed, relative humidity, solar radiation and air temperature
320 were monitored by Automated Weather Stations (AWS) within and outside of the study
321 catchment (Fig. 1). Of the climate and rainfall data used during the surface water modelling
322 (Watson et al., 2018), data was sourced from seven AWS's of which four stations were owned
323 by the South African Weather Service (SAWS) and three by the Agricultural Research Council
324 (ARC). Two stations that were installed for the surface water modelling, namely Moutonshoek
325 (M-AWS) and Confluence (CN-AWS) were used for climate and rainfall validation due to their
326 short record length. Additional rainfall data collected by farmers at high elevation at location
327 FF-R and within the middle of the catchment at KK-R were used to improve the climate and
328 rainfall network density.

329 Landuse classification: The vegetation and landuse dataset that was used for the sub-catchment
330 (CSIR, 2009) included five different landuse classes: 1) wetlands and waterbodies, 2)
331 cultivated (temporary, commercial, dryland), 3) shrubland and low fynbos, 4) thicket,
332 bushveld, bush clumps and high fynbos and 5) cultivated (permanent, commercial, irrigated).
333 Each different landuse class was assigned an albedo, root depth and seal grade value based on
334 previous studies (Steudel et al., 2015)(Supplementary: Table 2). The Leaf Area Index (LAI)
335 and vegetation height varies by growing season with different values of each for the particular
336 growing season. While surface resistance of the landuse varied monthly within the model, the
337 values only vary significantly between growing seasons.

338 Soil dataset: The Harmonized World Soil Database (HWSD) v1.2 (Batjes et al., 2012) was the
339 input soil dataset, with nine different soil forms within the sub-catchment (Supplementary:
340 Table 3). Within the HWSD, soil depth, soil texture and granulometry were used to calculate
341 and assign soil parameters within the J2000 model. MPS and LPS which differ in terms of the
342 soil structure and pore size were determined in Watson et al. (2018), using pedotransfer
343 functions within the HYDRUS model (Supplementary: Table 3).

344 Streamflow and water levels: Streamflow, measured at the Department of Water Affairs
345 (DWA) gauging station G3H001 between 1970-2009, at the outlet of Kruismans tributary (Het
346 Kruis) (Fig 1 and 3), was used for surface water calibration. The G3H001 two-stage weir could
347 record a maximum flow rate of $3.68 \text{ m}^2 \cdot \text{s}^{-1}$ due to the capacity limitations of the structure. After
348 2009, the G3H001 structure was decommissioned due to structural damage, although repairs
349 are expected in the near future due to increasing concerns regarding the influx of freshwater
350 into the lake. Water levels measured at the sub-catchment outlet at DWA station G3T001 (Fig
351 1) between 1994 to 2018 were used for EMD filtering.

352 **3.6.2 Groundwater parameters**

353 Net recharge and hydraulic conductivity: The hydraulic conductivity values used for the
354 groundwater component adaptation were collected from detailed MODFLOW modelling of
355 Krom Antonies tributary (Fig. 5) (Watson, 2018). The net recharge and aquifer hydraulic
356 conductivity for Krom Antonies tributary, was estimated through PEST autocalibration using
357 hydraulic conductivities from previous studies (SRK, 2009; UMVOTO-SRK, 2000) and
358 potential recharge estimates (Watson et al., 2018).

359 Hydrogeology: Within the hydrogeological dataset, parameters assigned include maximum
360 storage capacity (RG1 and RG2), storage coefficients (RG1 and RG2), the minimum
361 permeability/maximum percolation (Kf_geo of RG1 and RG2) and depth of the upper
362 groundwater reservoir (depthRG1). The maximum storage capacity was determined using an
363 average thickness of each aquifer and the total number of voids and cavities, where the primary
364 aquifer thickness was assumed to be between 15-20 m (Conrad et al., 2004), and the secondary
365 aquifer between 80-200 m (SRK, 2009). The maximum percolation of the different geological
366 formations was assigned hydraulic conductivities using the groundwater model for Krom
367 Antonies sub-catchment (Watson, 2018). The J2000 geological formations were assigned
368 conductivities to modify the maximum percolation value to ensure internal consistency with
369 recharge values calculated using MODFLOW (Table 1).

370 **3.7 J2000 model calibration**

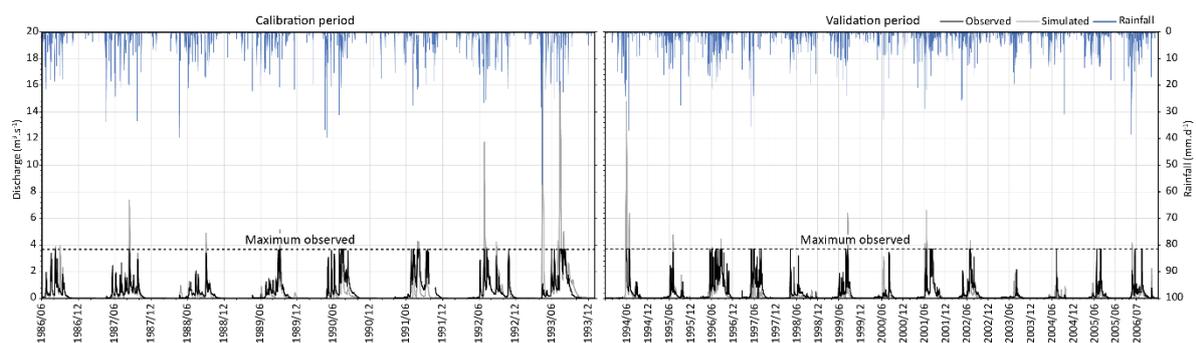

371 **3.7.1 Model sensitivity**

372 The J2000 sensitivity analysis for Verlorenvlei sub-catchment was presented in Watson *et al.*,
373 (2018) and therefore only a short summary is presented here. In this study, parameters that
374 were used to control the ratio of interflow to percolation were adjusted, which in the J2000
375 model include a slope (SoilLatVertDist) and max percolation value. The sensitivity analysis

376 conducted by Watson *et al.*, (2018) showed that for high flow conditions (E2) (Nash-Sutcliffe
 377 efficiency in its standard squared), model outputs are most sensitive to the slope factor, while
 378 for low flow conditions (E1) (modified Nash-Sutcliffe efficiency in a linear form) the model
 379 outputs were most sensitive to the maximum infiltration rate of the soil (ie. the parameter
 380 maxInfiltrationWet) (Supplementary: Figure 1). The max percolation was moderately sensitive
 381 during wet and dry conditions, and together with the slope factor, controlled the interflow to
 382 percolation proportioning that was calibrated in this study.

383 3.7.2 Surface water calibration

384 The surface water parameters of the model were calibrated for Kruismans tributary (688 km²)
 385 (Fig. 3) using the gauging data from G3H001 (Fig. 6 and Table 1). The streamflow data used
 386 for the calibration was between 1986-1993, with model validation between 1994 to 2007 (Fig.
 387 6). This specific calibration period was selected due to the wide range of different runoff
 388 conditions experienced at the station, with both low and high flow events being recorded. For
 389 the calibration, the modelled discharge was manipulated in the same fashion, with a DT limit
 390 (discharge table) of 3.68 m³/s, so that the tributary streamflow behaved as measured discharge.

391
 392 Figure 6: The surface water calibration (1986-1993) and validation (1994-2006) of the J2000
 393 model using gauging data from the G3H001

394 An automated model calibration was performed using the “Nondominating Sorting Genetic
 395 Algorithm II” (NSGA-II) multi-objective optimisation method (Deb *et al.*, 2002) with 1024

396 model runs being performed. Narrow ranges of calibration parameters (FC_Adaptation,
397 AC_Adaptation, soilMAXDPS, gwRG1Fact and gwRG2Fact) were chosen to (1) ensure that
398 the modelled recharge from J2000 was within an order of magnitude of recharge from the
399 MODFLOW model and previous studies; (2) achieve a representative sub-catchment
400 hydrograph. As objective functions, Nash-Sutcliffe-Efficiency based on absolute differences
401 (E1) and squared differences 2 (E2) as well as the average bias in % (Pbias) were utilized for
402 the calibration (Krause et al., 2005) (Table 2). The choice of the optimized parameter set was
403 made to ensure that E2 was better than 0.57 (best value was 0.57) and the Pbias better than 5
404 % (Table 1). From the automated calibration, 308 parameter sets were determined with the best
405 E1 being chosen to ensure that the model is representative of low flow conditions (Table 1).

406 ***3.7.3 Model validation***

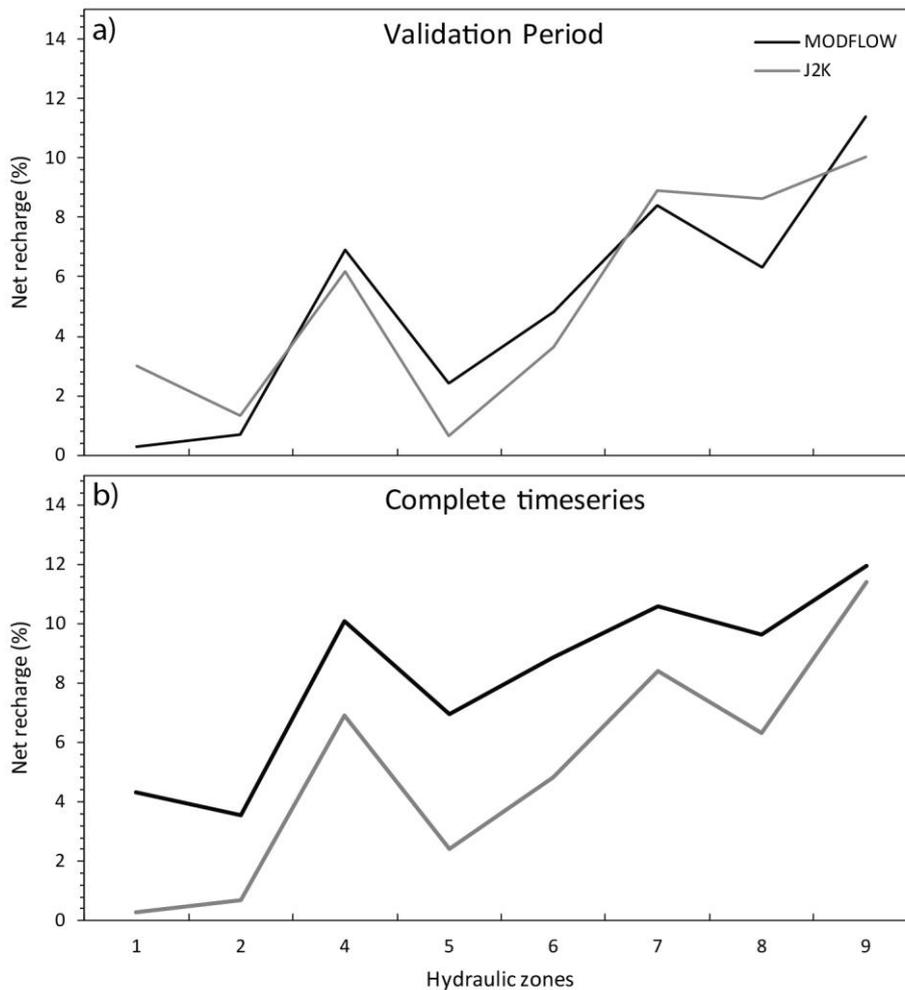

407 Observed vs modelled streamflow: For the surface water model validation, the streamflow
408 records between 1994-2007 were used, where Nash-Sutcliffe-Efficiency (E1 and E2) were
409 reported. The Pbias was also used as an objective function to report the model performance by
410 comparison between measured and modelled streamflow (Table 2). Although gauging station
411 limitations resulted in good objective functions from the model, the performance of objective
412 functions E1, E2, Pbias reduced between the validation and calibration period (Table 2). During
413 the calibration period there was a good fit between modelled and measured streamflow (Pbias=-
414 1.82), with a significant difference between modelled and measured streamflow during the
415 validation period (Pbias=-19.2). The calibration was performed over a wet cycle (1986-1997),
416 which resulted in a more common occurrence of streamflow events that exceeded $3.68 \text{ m}^3 \cdot \text{s}^{-1}$,
417 thereby reducing the number of calibration points. In contrast the validation was performed
418 over a dry cycle (1997-2007), which resulted in more data points as few streamflow events
419 exceeded $3.68 \text{ m}^3 \cdot \text{s}^{-1}$.

	Calibration 1987-1993	Validation 1994-2007
E1	0.55	0.53
E2	0.57	0.56
LogE1	0.28	0.10
LogE2	0.46	0.19
AVE	-19.24	-269.20
R ²	0.62	0.58
Pbias	-1.82	-19.23758
KGE	0.79	0.67417

420

421 Table 2: Value of the objective functions E1, E2, logarithmic versions of E1 and E2, absolute
422 volume error (AVE), coefficient of determination (R²), Pbias and Kling Gupta Efficiency
423 (KGE) (Gupta et al., 2009) for surface water calibration (1987-1993) and validation (1994-
424 2007)

425 The J2000 and MODFLOW recharge estimates: With adjustment of hydraulic conductivities
426 from MODFLOW to J2000 it was possible to converge the net recharge estimates between 1.3
427 % with a range of recharge of 0.65-10.03 % for the J2000 and 0.3-11.40 % for MODFLOW.
428 Recharge estimates from previous studies of the primary aquifer indicate recharge rates of 0.2-
429 3.4 % (Conrad et al., 2004), and 8 % Vetger, 1995, while for the TMG aquifer 13 % (Wu,
430 2005), 27 % (Miller et al., 2017) and 17.4 % (Weaver and Talma, 2005) of MAP. J2000
431 estimates had an average value of 5.30 % while MODFLOW was 5.20% for the eight hydraulic
432 zones of Krom Antonies. The coefficient of determination (R²) between net recharge from the
433 J2000 and MODFLOW was 0.81. Across the entire dataset J2000 overestimated groundwater
434 recharge by 2.75 % relative to MODFLOW, although the coefficient of determination produced
435 an R² of 0.92 which is better than during the validation period.

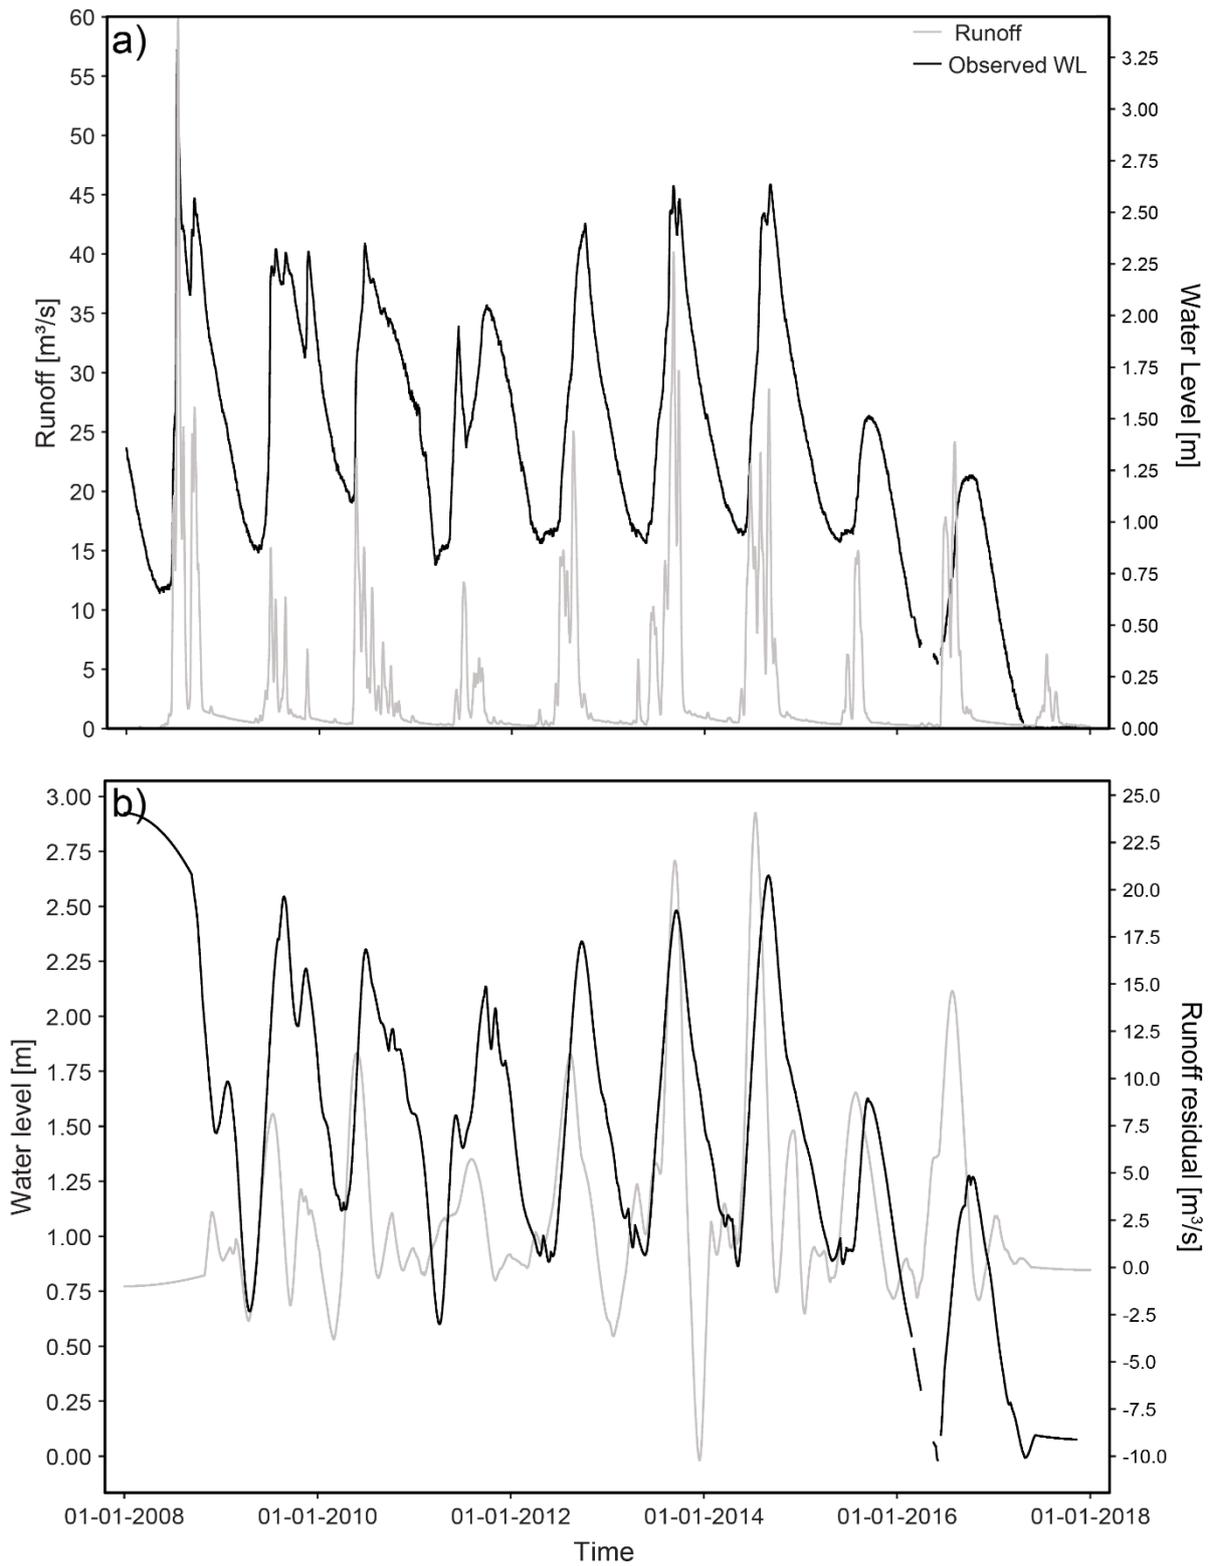

436

437 Figure 7: The groundwater calibration for each hydraulic zone with a) net recharge for the
 438 J2000 and MODFLOW during the model calibration (2016) and b) the net recharge deviation
 439 between MODFLOW and J2000 across the entire modelling timestep (1986-2017)

440 **3.8 EMD filtering**

441 To account for missing streamflow data between 2007-2017, an Empirical Mode
 442 Decomposition (EMD) (Huang et al., 1998) was applied to the measured water level data at
 443 the sub-catchment outlet (G3T001)(Fig. 1) between 1994 to 2018 (Fig 8a). EMD is a method
 444 for the decomposition of nonlinear and nonstationary signals into sub-signals of varying
 445 frequency, so-called intrinsic mode functions (IMF), and a residuum signal. By removing one
 446 or more IMF or the residuum signal, certain frequencies (e.g. noise) or an underlying trend can

447 be removed from the original time series data. This approach was successfully applied to the
448 analysis of river runoff data (Huang et al., 2009) and forecasting of hydrological time series
449 (Kisi et al., 2014). In this study, EMD filtering was used to remove high frequency sub-signals
450 from simulated runoff and measured water level data to compare the more general seasonal
451 variations of both signals (Fig. 8b).

452

453 Figure 8: a) The water level fluctuations at station G3T001 with modelled runoff and b) the

454 EMD filtering showing the variation in discharge timeseries attributed a water level change at

455 the station

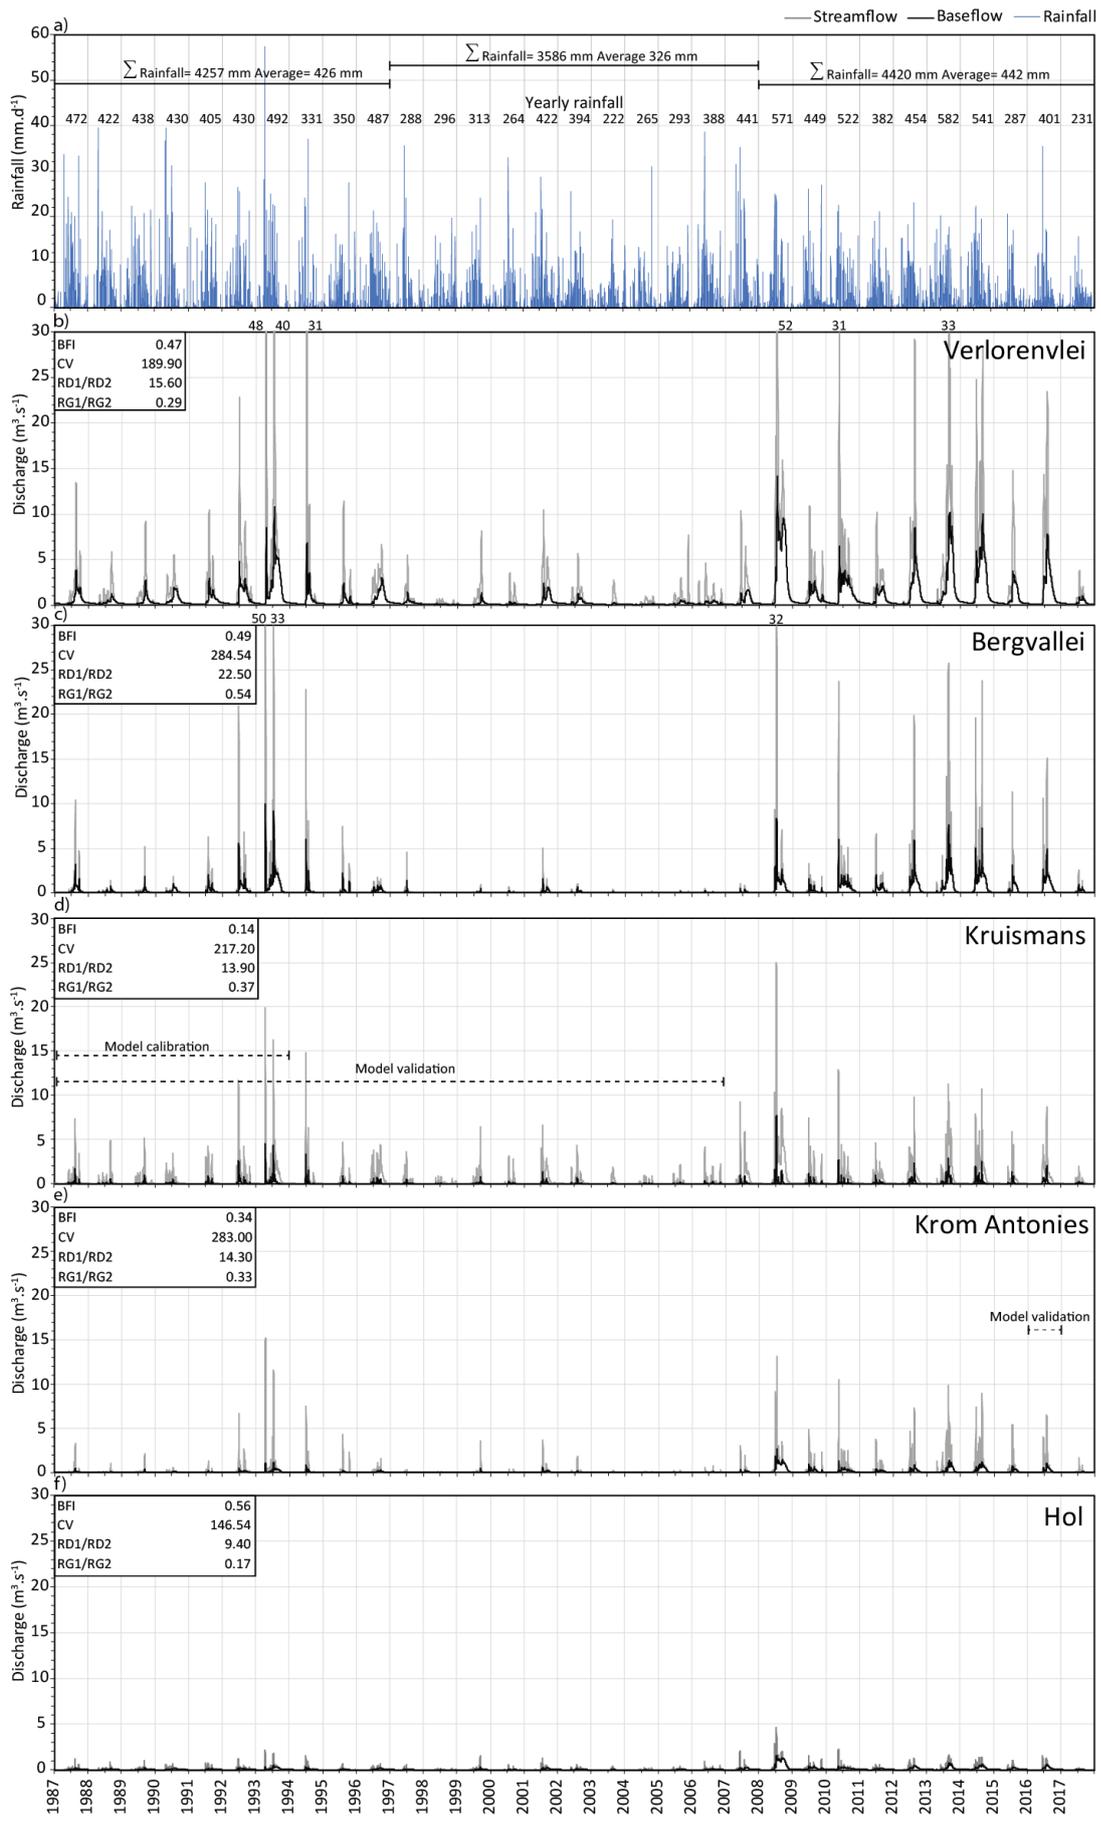

456 **4. Results**

457 The J2000 model was used to simulate both runoff and baseflow, with runoff being comprised
458 of direct surface runoff (RD1) and interflow (RD2) and baseflow simulated from the primary
459 (RG1) and secondary aquifer (RG2). Below, the results of the modelled streamflow and
460 baseflow are presented, along with the total flow contribution of each tributary, the runoff to
461 baseflow proportioning and stream exceedance probabilities. The coefficient of variation (CV)
462 was used to determine the streamflow variability of each tributary, while the baseflow index
463 (BFI) was used to determine the baseflow and runoff proportion.

464 **4.1 Streamflow and baseflow**

465 Streamflow for the sub-catchment shows two distinctively wet periods (1987-1996 and 2008-
466 2017), separated by a dry period (1997-2007) (Fig. 9). Yearly sub-catchment rainfall volumes
467 between 1987-1996 were between 288 and 492 mm/yr⁻¹, with an average of 426 mm.yr⁻¹ and
468 standard deviation (STD) of 51 mm.yr⁻¹. For this period, average yearly streamflow was 1.4
469 m³.s⁻¹, with an average baseflow contribution of 0.63 m³.s⁻¹. The modelled streamflow reached
470 a maximum of 48 m³.s⁻¹ in 1993, where 5 m³.s⁻¹ of baseflow was generated after 58 mm of
471 rainfall was received. Between 1997-2007 (dry period) sub-catchment yearly rainfall was
472 between 222 and 394 mm/yr⁻¹ with an average of 326 mm.yr⁻¹ and STD of 69 mm.yr⁻¹ (Fig.
473 9). For this same period, average yearly streamflow was 0.44 m³.s⁻¹, with an average baseflow
474 contribution of 0.18 m³.s⁻¹. The modelled streamflow reached a maximum of 11 m³.s⁻¹ in 2002,
475 with a baseflow contribution of 2.5 m³.s⁻¹ after 28 mm of rainfall was received. During the
476 second wet period between 2008-2017 sub-catchment yearly rainfall was between 231 and 582
477 mm.yr⁻¹ with an average of 442 mm.yr⁻¹ and STD of 112 mm.yr⁻¹ (Fig. 9). Over this same
478 period, average yearly streamflow was 2.5 m³.s⁻¹ with an average baseflow contribution of 1.3

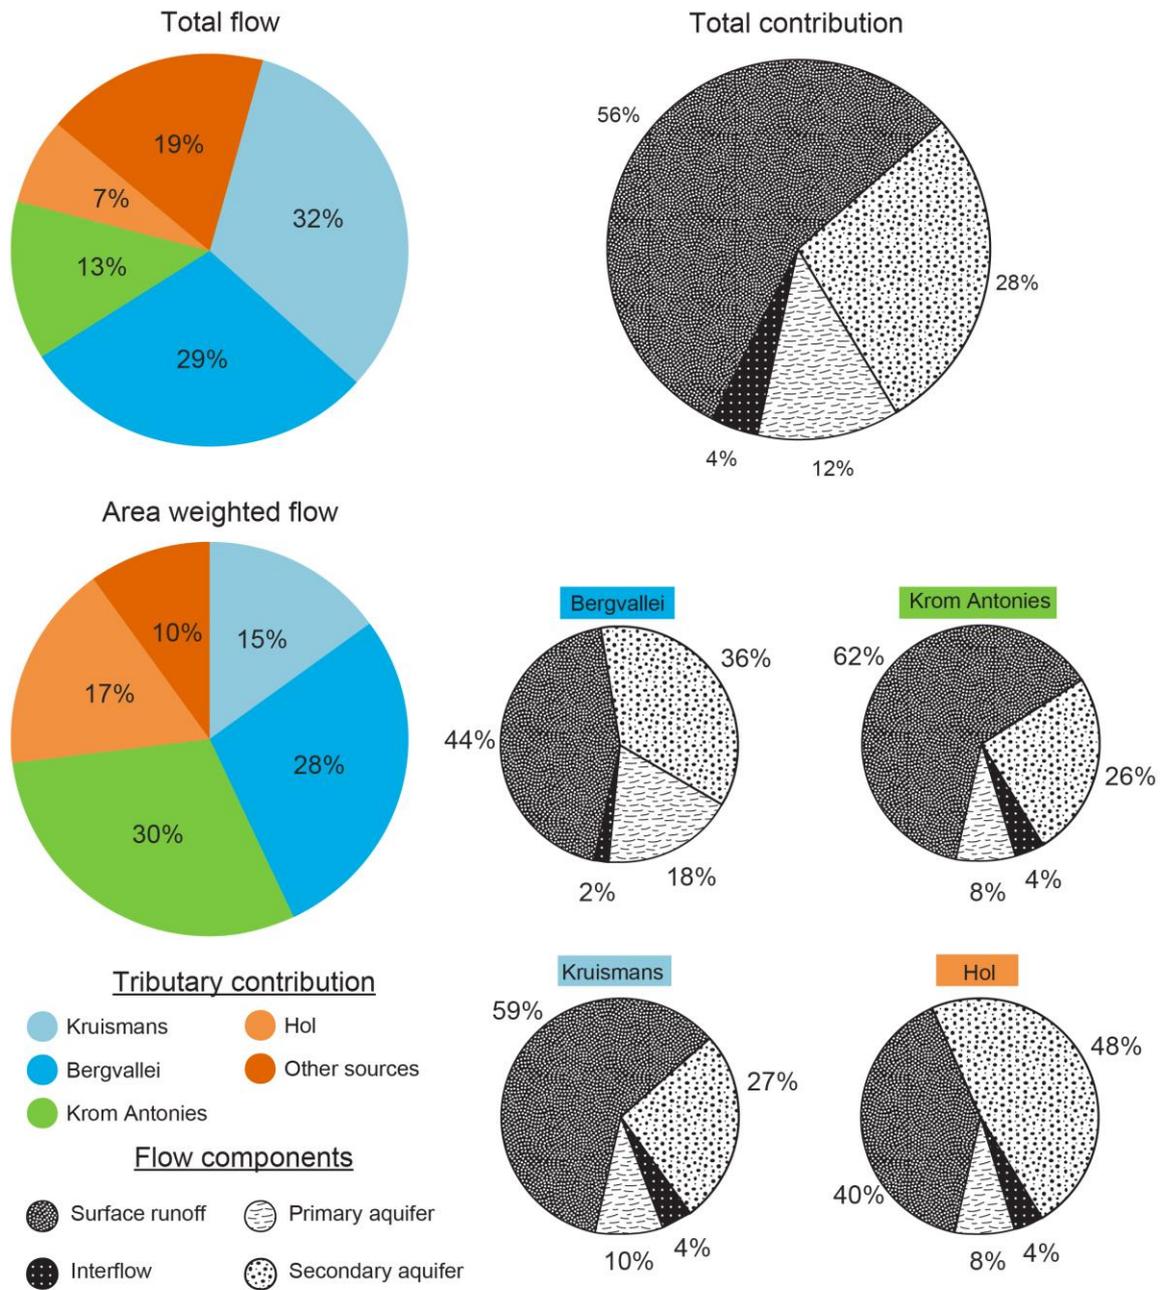

479 $\text{m}^3.\text{s}^{-1}$. The modelled streamflow reached a maximum of $52 \text{ m}^3.\text{s}^{-1}$ in 2008, with $13 \text{ m}^3.\text{s}^{-1}$ of
480 baseflow generated after two consecutive rainfall events each of 25 mm.

482 Figure 9: a) Average sub-catchment rainfall between 1987-2017 showing wet cycles (1987-
483 1997 and 2008-2017) and dry cycle (1997-2007), Modelled streamflow and baseflow inflows
484 for the b) Verlorenvlei, c) Bergvallei, d) Kruismans, e) Krom Antonies and f) Hol tributaries
485 with estimated BFI, CV, RD1/RD2, RG1/RG2

486 **4.2 Tributary contributions**

487 The four main feeding tributaries (Bergvallei, Kruismans, Hol and Krom Antonies) together
488 contribute 81 % of streamflow for the Verlorenvlei, with the additional 19 % from small
489 tributaries near Redelinghuys (Fig. 10). Kruismans contributes most of the total streamflow at
490 32 %, but only 15 % of the area-weighted contribution as its sub-catchment is the largest of the
491 four tributaries at 688 km² (Fig. 10). Bergvallei with a sub-catchment of 320 km², contributes
492 29 % of the total flow with an area weighted contribution of 28 %. Krom Antonies has the
493 largest area weighted contribution of 30 % due to its small size (140 km²) in comparison to the
494 other tributaries, although Krom Antonies contributes only 13 % of the total flow (Fig. 10).
495 Hol sub-catchment at 126 km² makes up the smallest contribution to the total flow of only 7
496 %, but has a weighted contribution of 17 % (Fig. 10).

497

498 Figure 10: The Verlorenvlei reserve flow contributions (total flow and area weighted flow) of
 499 Kruismans, Bergvallei, Krom Antonies and Hol as well as flow component separation into
 500 surface runoff (RD1), interflow (RD2), primary aquifer flow (RG1) and secondary aquifer
 501 flow (RG2).

502 **4.3 Flow variability**

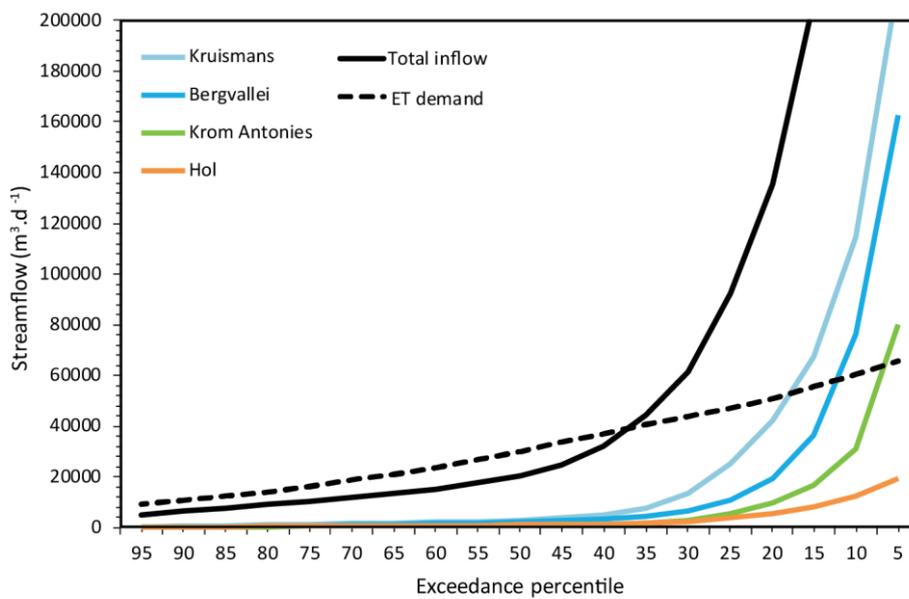

503 Streamflow that enters Verlorenvlei has a large daily variability with a coefficient of variation
504 (CV) of 189.90 (Fig. 9). This is mainly due to high streamflow variability from Kruismans (32
505 %) with a CV of 217.20, which is the major total flow contributor (Fig 10). Bergvallei and
506 Krom Antonies, which both have high streamflow variability with CV values of 284.54 and
507 283.00 respectfully (Fig. 9), further contribute to the high variability of streamflow that enters
508 the lake. While Hol reduces the overall streamflow variability with a CV of 146.54, it is a minor
509 total flow contributor (7 %) and therefore does not reduce the overall streamflow variability
510 significantly (Fig. 10).

511 Streamflow that enters Verlorenvlei is dominated by surface runoff which makes up 56 % of
512 total flow, with groundwater and interflow contributing 40 % and 4 % respectfully (Fig. 10).
513 The large surface runoff dominance in streamflow entering the lake, is due to a high surface
514 runoff contribution from Kruismans and Krom Antonies, which contribute 26 % of total flow
515 from surface runoff. However, for Bergvallei and Hol, surface runoff contributions are less
516 dominant with 16 % of the total, while the total groundwater contribution is 20 % from these
517 tributaries. Across all four tributaries, the secondary aquifer is the dominant baseflow
518 component with 28 % of total flow, with the primary aquifer contributing 12 %. Bergvallei and
519 Kruismans contribute the majority of primary aquifer baseflow with 8 % of the total. The
520 secondary aquifer baseflow is mainly contributed by Kruismans and Bergvallei, where together
521 18 % of the total is received. Interflow across the four tributaries is uniformly distributed with
522 0.3 – 1 % of the total flow being contributed from each tributary.

523 **4.4 Flow exceedance probabilities**

524 The flow exceedance probability, which is a measure of how often a given flow is equalled or
525 exceeded was calculated for each of the tributaries as well as the lake water body. The results

526 for the flow exceedance probabilities includes flow volumes which are exceeded 95 %, 75 %,
 527 50 %, 25 % and 5 % of the time. The 95 percentile corresponds to a lake inflow of $0.054 \text{ m}^3 \cdot \text{s}^{-1}$
 528 1 or $4,702 \text{ m}^3 \cdot \text{d}^{-1}$, with between $0.001\text{-}0.004 \text{ m}^3 \cdot \text{s}^{-1}$ from the feeding tributaries (Fig. 11 and
 529 Table 3). The 75-percentile flow, which is exceeded 3/4 of the time corresponds to an inflow
 530 of $0.119 \text{ m}^3 \cdot \text{s}^{-1}$ or $10,303 \text{ m}^3 \cdot \text{d}^{-1}$, with between $0.005\text{-}0.015 \text{ m}^3 \cdot \text{s}^{-1}$ from the feeding tributaries.
 531 Average (50 percentile) streamflow flowing into the Verlorenvlei is $0.237 \text{ m}^3 \cdot \text{s}^{-1}$ or $20,498$
 532 $\text{m}^3 \cdot \text{d}^{-1}$, with between $0.010\text{-}0.035 \text{ m}^3 \cdot \text{s}^{-1}$ from the feeding tributaries. The 25-percentile flow,
 533 which is exceeded $\frac{1}{4}$ of the time corresponds to a lake inflow of $1,067 \text{ m}^3 \cdot \text{s}^{-1}$ or $92,204 \text{ m}^3 \cdot \text{d}^{-1}$
 534 with between $0.044\text{-}0.291 \text{ m}^3 \cdot \text{s}^{-1}$ from the feeding tributaries. The lake inflows that are
 535 exceeded 5 % of the time correspond to $6.939 \text{ m}^3 \cdot \text{s}^{-1}$ or $599,535 \text{ m}^3 \cdot \text{d}^{-1}$ with between 0.224-
 536 $2.49 \text{ m}^3 \cdot \text{s}^{-1}$ from the feeding tributaries.

540

541 Table 3: The streamflow exceedance percentiles and lake evaporation demand for the
542 Verlorenvlei reserve, with the contributions from Kruismans, Bergvallei, Krom Antonies and
543 Hol (m³.s⁻¹ and m³.d⁻¹)

544 5. Discussion

545 The adaptation of the J2000 rainfall/runoff model was used to understand the flow
546 contributions of the main feeding tributaries, the proportioning of baseflow to surface runoff
547 as well as how often the inflows exceed the lake evaporation demand. Before a comparison
548 with previous baseflow estimates can be made and the impact of evaporation on the lake
549 reserve, the model limitations and catchment flow dynamics must also be assessed.

550 5.1 Model limitations and performance

551 A major limitation facing the development and construction of comprehensive modelling
552 systems in sub-Saharan Africa is the availability of appropriate climate and streamflow data.
553 For this study, while there was access to over 20 years of streamflow records, the station was

554 only able to measure a maximum of $3.68 \text{ m}^3\cdot\text{s}^{-1}$, which hindered calibration of the model for
555 high flow events. As such, the confidence in the model's ability to simulate high streamflow
556 events using climate records is limited. While the availability of measured data is a limitation
557 that could affect the modelled streamflow, discontinuous climate records also hindered the
558 estimations of long time series streamflow.

559 Over the course of the 31-year modelling period, a number of climate stations used for
560 regionalisation were decommissioned and were replaced by stations in different areas. This
561 required adaption of climate regionalisation for simulations over the entire 31-year period to
562 incorporate the measured streamflow from the gauging station. To account for missing
563 streamflow records since 2007, an EMD filtering protocol was applied to the runoff data (Fig.
564 6). The results from the EMD filtering showed that after removing the first nine IMFs, the local
565 maxima of both signals match the seasonal water level maxima during most of the years. While
566 considerable improvement can be made to the EMD filtering, the results show some agreement
567 which suggested that the simulated runoff was representative of inflows into the lake.

568 **5.2 Catchment dynamics**

569 Factors that impact streamflow variability are important for understanding river flow regime
570 dynamics. Previously, factors that affected streamflow variability such as CV and BFI values
571 were used to determine how susceptible particular river systems were to drought (e.g Hughes
572 and Hannart, 2003). While CV values have been used to account for climatic impacts such as
573 dry and wet cycles, BFI values are associated with runoff generation processes that impact the
574 catchment. For most river systems, BFI values are generally below 1 implying that runoff
575 exceeds baseflow. In comparison CV values can be in excess of 10 implying high variability
576 in streamflow volumes (Hughes and Hannart, 2003). In this study, these two measurements

577 have been applied to tributaries as opposed to quaternary river systems, to understand the
578 streamflow input variability into the Verlorenvlei.

579 The highest proportion of streamflow needed to sustain the Verlorenvlei lake water level is
580 received from the Bergvallei tributary, although the area weighted contribution from Krom
581 Antonies is more significant (Fig. 10). However, CV values for the Bergvallei indicate high
582 streamflow variability. This is partially due to the high surface runoff component in modelled
583 streamflow within the Bergvallei in comparison to the minor interflow contribution, suggesting
584 little sub-surface runoff. While streamflow from the Bergvallei tributary is 54 % groundwater,
585 which would suggest a more sustained streamflow, due to the TMG dominance as well as a
586 high primary aquifer contribution, baseflow from the Bergvallei is driven by highly conductive
587 rock and sediment materials. Similarly, CV values for Krom Antonies indicate high streamflow
588 variability due to the presence of a high baseflow contribution from the conductive TMG and
589 primary aquifers. Although Krom Antonies has a larger interflow component, which would
590 reduce streamflow variability, the dominant TMG presence within this tributary partially
591 compensates for the subsurface flow contributions.

592 In contrast, Hol has a much smaller daily streamflow variability in comparison to both
593 Bergvallei and Krom Antonies (Fig. 9). While streamflow from Hol tributary is mainly
594 comprised of baseflow (56 %), the dominance of low conductive shale rock formations as well
595 as a large interflow component results in reduced streamflow variability. While the larger shale
596 dominance in this tributary not only results in a more sustained baseflow from the secondary
597 aquifer, it also results in a large interflow component due to the limited conductivity of the
598 shale formations. Compounding the more sustained baseflow from Hol tributary, the reduced
599 extent of the primary aquifer results in a dominance in slow groundwater flow from this
600 tributary. Similarly, Kruismans is dominated by shale formations which result in a larger

601 interflow contribution, although due to the limited baseflow contribution (37 %) the streamflow
602 from this tributary is highly variable, which impacts on its susceptibility to drought.

603 The results from this study have shown that while Krom Antonies was initially believed to be
604 the major flow contributor, Bergvallei is in fact the most significant, although streamflow from
605 the four tributaries is highly variable, with baseflow from Hol tributary the only constant input
606 source. The presence of conductive TMG sandstones and quaternary sediments in both Krom
607 Antonies and Bergvallei, results in quick baseflow responses with little flow attenuation. The
608 potential implication of a constant source of groundwater being provided from Hol tributary,
609 is that if the groundwater is of poor quality this would result in a constant input of saline
610 groundwater, with Krom Antonies and Bergvallei providing freshwater only after sufficient
611 rainfall has been received.

612 **5.3 Baseflow comparison**

613 The groundwater components of the J2000 model were adjusted using aquifer hydraulic
614 conductivity from a MODFLOW model of one of the main feeding tributaries of the
615 Verlorenvlei. Krom Antonies was selected as it was previously believed to be the largest input
616 of groundwater to Verlorenvlei (Fig. 2). Baseflow for Krom Antonies tributary was previously
617 calculated using a MODFLOW model (Watson, 2018), by considering aquifer hydraulic
618 conductivity and average groundwater recharge. As average recharge was used, baseflow
619 estimates from MODFLOW are likely to fall on the upper end of daily baseflow values
620 estimated by the J2000 model. For Krom Antonies sub-catchment, Watson, (2018) estimated
621 baseflow between 14,000 to 19,000 m³.d⁻¹ for 2010-2016 using MODFLOW. Similar daily
622 baseflow estimates from the J2000 were only exceeded 10 % of the time, with average
623 estimates (50 %) of 1,036 m³.d⁻¹ over the course of the modelling period (Fig. 9).

624 The MODFLOW estimates were applied over the course of a wet cycle (2016). In comparison
625 to the MODFLOW estimates (14,000 to 19,000 m³.d⁻¹) average baseflow from J2000 for 2016
626 was 8, 214 m³.d⁻¹. The daily timestep nature of the J2000 is likely to result in far lower baseflow
627 estimates, as recharge is only received over a 6-month period as opposed to a yearly average
628 estimate. One possible implication of this is that while common groundwater abstraction
629 scenarios have been based on yearly recharge, abstraction is likely to exceed sustainable
630 volumes during dry months or dry cycles and this could hinder the ability of the aquifer to
631 supply baseflow. While the groundwater components of the J2000 have been distributed to
632 allow for improved baseflow estimates, the groundwater calibration was applied to Krom
633 Antonies. However, this study showed that Bergvallei has been identified as the largest water
634 contributor. In hindsight, the use of geochemistry to identify dominant tributaries could have
635 aided the groundwater model adaption. While it would have been beneficial to adapt the
636 groundwater components of the J2000 using the dominant baseflow contributor, considering
637 the geological heterogeneity between tributaries is more important for identifying how to adapt
638 the groundwater components of the J2000. While the distribution of aquifer components
639 improved modelled baseflow, including groundwater abstraction scenarios in baseflow
640 modelling in the sub-catchment is important for future water management for this ecologically
641 significant area.

642 **5.4 The Verlorenvlei reserve and the evaporative demand**

643 For this study, exceedance probabilities were estimated through rainfall/runoff modelling for
644 the previous 31 years within the Verlorenvlei sub-catchment. The exceedance probabilities
645 were determined for each tributary, as well as the total inflows into the lake. These exceedance
646 probabilities were compared with the evaporative demand of the lake, to understand whether
647 inflows are in surplus or whether the evaporation demand exceeds inflow.

648 From the exceedance probabilities generated in this study, the lake is predominately fed by less
649 frequent large discharge events, where on average the daily inflows to the lake do not sustain
650 the lake water level. This is particularly evident in the measured water level data from station
651 G3T001, where measured water levels have a large daily standard deviation (0.62) (Watson *et*
652 *al.*, 2018). The daily inflows of water into the Verlorenvlei has also been subject to significant
653 rainfall variability, with yearly rainfall between the second wet cycle (2007-2017) being twice
654 as variable in comparison to the first wet cycle (1987-1996). The change in rainfall variability
655 has had a significant impact on soil moisture conditions, resulting in not only larger peak
656 discharges but also lengthened low flow conditions. With climate change likely to impact the
657 length and severity of dry cycles, it is likely that the lake will dry up more frequently into the
658 future, which could have severe implications on the biodiversity that relies on the lake's habitat
659 for survival. Of importance to the lake's survival is the protection of river inflows during wet
660 cycles, where the lake requires these inflows for regeneration.

661 While the impact of irrigation could not be incorporated, over allocation of water resources
662 may potentially have a significant impact on the catchment water balance, especially during
663 wet cycles when ecosystems are recovering from dry conditions. The increased irrigation
664 during wet cycles as a result of agricultural development, could be a further impact on the
665 recovery of sensitive ecosystems. This type of issue is not limited to Verlorenvlei but applies
666 to many wetlands or estuarine lakes around the world, while they have been classified as
667 protected areas, water resources within the catchments are required for food security. As
668 climate change drives increased temperatures and variability in rainfall, the \pm 10-year cycles
669 of dry and wet conditions may no longer be valid anymore, where these conditions may shorten
670 or lengthen. With the routine breaking of weather records across the world (Bruce, 2018; Davis,
671 2018), it is becoming increasingly evident that conditions are changing and becoming more

672 variable, which could impact sensitive ecosystems around the world, highlighting the need for
673 effective water management protocols during times of limited rainfall.

674

675 **6. Conclusion**

676 Understanding river flow regime dynamics is important for the management of ecosystems that
677 are sensitive to streamflow fluctuations. While climatic factors impact rainfall volumes during
678 wet and dry cycles, factors that control catchment runoff and baseflow are key to the
679 implementation of river protection strategies. In this study, groundwater components within
680 the J2000 model were distributed to improve baseflow and runoff proportioning for the
681 Verlorenvlei sub-catchment. The J2000 was distributed using groundwater model values for
682 the dominant baseflow tributary, while calibration was applied to the dominant streamflow
683 tributary. The model calibration was hindered by the DT limit, which reduced the confidence
684 in modelling high flow events, although an EMD filtering protocol was applied to account for
685 the resolution limitations and missing streamflow records. The modelling approach would
686 likely be transferable to other partially gauged semi-arid catchments, provided that
687 groundwater recharge is well constrained. The daily timestep nature of the J2000 model
688 allowed for an in-depth understanding of tributary flow regime dynamics, showing that while
689 streamflow variability is influenced by the runoff to baseflow proportion, the host rock or
690 sediment in which groundwater is held is also a factor that must be considered. The modelling
691 results showed that on average the streamflow influxes were not able to meet the evaporation
692 demand of the lake, with yearly rainfall becoming more variable. High-flow events, although
693 they occur infrequently, are responsible for regeneration of the lake's water level and ecology,
694 which illustrates the importance of wet cycles in maintaining biodiversity levels in semi-arid
695 environments. With climate change likely to impact the length and occurrence of dry cycle
696 conditions, wet cycles become particularly important for ecosystem regeneration, especially
697 for semi-arid regions such as the Verlorenvlei.

698 **7. Acknowledgements**

699 The authors would like to thank the WRC and SASSCAL for project funding as well as the
700 NRF and Iphakade for bursary support. Agricultural Research Council (ARC) and South
701 African Weather Service (SAWS) for their access to climate and rainfall data. The research
