14  
15 **Abstract:** The Paris Agreement sets a long-term temperature goal to hold global  
16 warming to well below 2.0°C and strives to limit to 1.5°C above preindustrial levels.  
17 Droughts with either intense severity or a long persistence could both lead to substantial  
18 impacts such as infrastructure failure and ecosystem vulnerability, and they are  
19 projected to occur more frequently and trigger intensified socioeconomic consequences  
20 with global warming. However, existing assessments targeting global droughts under  
21 1.5°C and 2.0°C warming levels usually neglect the multifaceted nature of droughts  
22 and might underestimate potential risks. This study, within a bivariate framework,  
23 quantifies the change of global drought conditions and corresponding socioeconomic  
24 exposures for additional 1.5°C and 2.0°C warming trajectories. The drought  
25 characteristics are identified using the Standardized Precipitation Evapotranspiration  
26 Index (SPEI) combined with the run theory, with the climate scenarios projected by 13  
27 Coupled Model Inter-comparison Project Phase 5 (CMIP5) global climate models  
28 (GCMs) under three representative concentration pathways (RCP2.6, 4.5 and 8.5). The  
29 copula functions and the most likely realization are incorporated to model the joint  
30 distribution of drought severity and duration, and changes in the bivariate return period  
31 with global warming are evaluated. Finally, the drought exposures of populations and

1 regional gross domestic product (GDP) under different shared socioeconomic pathways  
2 (SSPs) are investigated globally. The results show that within the bivariate framework,  
3 the historical 50-year droughts may double across 58% of global landmasses in a 1.5°C  
4 warmer world, while when the warming climbs up to 2.0°C, an additionally 9% of world  
5 landmasses would be exposed to such catastrophic drought deteriorations. More than  
6 75 (73) countries' population (GDP) will be completely affected by increasing drought  
7 risks under the 1.5°C warming, while an extra 0.5°C warming will further lead to an  
8 additional 17 countries suffering from a nearly unbearable situation. Our results  
9 demonstrate that limiting global warming to 1.5°C, compared with 2°C warming, can  
10 perceptibly mitigate the drought impacts over major regions of the world.

## 14 **1. Introduction**

15 Climate warming mainly due to greenhouse gas emissions has altered the global  
16 hydrological cycle and resulted in more frequent and persistent natural hazards such as  
17 droughts, which have imposed considerable economic, societal, and environmental  
18 challenges across the globe (Handmer et al., 2012; Chang et al., 2016; EM-DAT 2017).  
19 With the aspiration to mitigate these adverse consequences, the Paris Agreement  
20 proposed to cut greenhouse gas emissions for holding the increase in global temperature  
21 to well below 2.0°C and pursuing efforts, limiting the warming to 1.5°C above pre-  
22 industrial levels (UNFCCC, 2015). Regardless of the socioeconomic and technological  
23 achievability of the Paris Agreement goals, portraying the drought evolution with  
24 different warming trajectories would provide valuable information and references for  
25 mankind to enable appropriate adaptation strategies in a warmer future.

26 To examine the sensitivity of drought risks with different warming targets,  
27 numerous approaches have emerged. One way is to employ a set of ensemble  
28 simulations produced by a single coupled climate model (e.g., Community Earth

1 System Model, CESM), which is designed specifically to perform the impact  
2 assessments at a near-equilibrium scenarios of 1.5°C or 2°C additional warming  
3 (Sanderson et al., 2017; Lehner et al., 2017). This single model type cannot reflect the  
4 structural uncertainty of climate models, which is important in impact assessments, and  
5 thus raises doubts about the robustness of such drought condition assessments (Liu et  
6 al., 2018a). Emerging modeling efforts such as the “Half a degree Additional warming,  
7 Projections, Prognosis and Impacts” (HAPPI) model inter-comparison project provided  
8 a new dataset with experiments designed to explicitly target impacts of 1.5°C and 2°C  
9 above preindustrial warming (Mitchell et al., 2016). However, the HAPPI employed  
10 prescribed climatological sea surface temperatures and could not consider the internal  
11 variability of ocean-atmosphere circulation, which is crucial in physically simulating  
12 climatic variability and persistence (Seager et al., 2005; Routson et al., 2016). Current  
13 studies usually utilize CMIP5 climate models to project climate scenarios under  
14 different RCPs, identify the time period for a warming target and then examine the  
15 drought conditions associated with different levels of global warming. For instance, Su  
16 et al. (2018) used 13 CMIP5 models based on RCP 2.6 and RCP 4.5 to compare the  
17 drought conditions for two warming targets over China and reported tremendous losses  
18 will emerge even under the ambitious 1.5°C warming target.

19 These prevailing tides of literature almost reach a consensus that, with higher  
20 saturation threshold and more intense and frequent dry spells driven by rising  
21 temperatures, drought conditions would considerably worsen in many regions of the  
22 world (Mitchell et al., 2016; Liu et al., 2018a, b). The potentially devastating impacts  
23 of more severe drought conditions on society raise considerable concerns, motivating a  
24 number of global socioeconomic assessments of future drought change impact (e.g.,  
25 Below et al., 2007; Schilling et al., 2012). For instance, Liu et al. (2018a) investigated  
26 global drought evolution and corresponding population exposures in additional 1.5°C  
27 and 2°C warming conditions using a set of CMIP5 models under RCP 4.5 and RCP 8.5.  
28 Naumann et al. (2018) assessed the development of drought conditions across the world  
29 for different warming targets in the Paris Agreement. These studies concluded that there

1 are considerable benefits for the environment and society of limiting warming to 1.5°C  
2 relative to 2.0°C, although 1.5°C warming still implies a substantial challenge for global  
3 sustainable development. However, most previous socioeconomic assessments (e.g.,  
4 Peters, 2016; Park et al., 2018; Liu et al. 2019) have focused on a static socioeconomic  
5 scenario, probably due to data constraint. These studies cannot capture the dynamic  
6 nature of population and assets over time, that has been identified as crucial for  
7 simulating realistic societal development path (Smirnov et al., 2016). Recently, five  
8 Shared Socioeconomic Pathways (SSPs) have been proposed, providing a more  
9 reasonable dataset to characterize a set of plausible alternative futures of societal  
10 development with consideration of climate change and policy impacts over the 21st  
11 century (Leimbach et al., 2017). To date, the SSPs have not yet been incorporated into  
12 the drought impact assessments with warming at the global scale.

13 More importantly, among existing global drought impact assessments, especially  
14 those targeting different warming levels proposed by the Paris Agreement, drought  
15 variables such as severity and duration are usually separately investigated through  
16 probability modelling and stochastic theories (e.g., Sanderson et al., 2017; Lehner et al.,  
17 2017; Su et al., 2018). Knowing that droughts are multifaceted phenomena (Xu et al.,  
18 2015; Tsakiris et al., 2016) usually characterized by duration and severity, univariate  
19 frequency analysis is unable to describe the probability of occurrence for the drought  
20 events physically and may lead to underestimation of drought risks and societal hazards.  
21 For instance, droughts with a moderate severity but a long persistence are seldom  
22 identified as severe events in univariate analysis; nevertheless, they may pose  
23 substantial socioeconomic losses because of rapid stored water depletion and low  
24 resilience to subsequent droughts (Lehner et al., 2017). Therefore, there is an urgent  
25 necessity to incorporate the joint modeling of multiple drought features into impact  
26 assessments (Genest et al., 2007; Liu et al., 2015). The copula function that shows good  
27 feasibility of marginal distributions in modeling inter-correlated variables has been  
28 introduced in multivariate analysis for droughts (e.g., Wong et al. 2013; Zhang et al.  
29 2015; Ayantobo et al., 2017). However, to the authors' knowledge, no previous work

1 links the high interdependence of drought characteristics to a global impact assessment  
2 under different warming levels.

3 In the multivariate framework, selection of variable combinations along the  
4 quantile curve poses a new challenge, as the choice of the joint return period (JRP) leads  
5 to infinitely many such combinations. To meet the needs of infrastructure design and  
6 adaptivity, many researchers (e.g., Chen et al. 2010; Li et al. 2016; Zscheischler et al.,  
7 2017) have assumed that the correlated variables have the same probability of  
8 occurrence under a given JRP, which is called the equivalent frequency combination  
9 (EFC) method. Despite the fact that the EFC method has low calculation complexity,  
10 the statistical and theoretical basis of the equal frequency assumption is questionable  
11 (Yin et al. 2018a). To develop a more rational design for a multivariate approach, a  
12 novel concept of “most likely design realization” to choose the point with the highest  
13 likelihood along the quantile curve has been proposed in frequency analysis (Salvadori  
14 et al. 2011; Yin et al. 2019). It would be very important to evaluate and characterize  
15 these different likelihoods of drought events in bivariate drought impact assessment  
16 under a warming climate.

17 In this study, under a bivariate framework, we quantify changes in global drought  
18 conditions and socioeconomic exposure with additional levels of 1.5°C and 2.0°C  
19 warming. The drought characteristics are identified using the Standardized  
20 Precipitation Evapotranspiration Index (SPEI) combined with the run theory and with  
21 climate scenarios simulated by 13 CMIP5 GCMs under three RCPs (RCP2.6, 4.5, and  
22 8.5). The copula functions and most likely realization are incorporated to model the  
23 drought severity and duration concurrently, and changes in the bivariate return period  
24 with global warming are systematically investigated. Finally, the drought exposures of  
25 populations and regional GDP under different shared socioeconomic pathways (SSPs)  
26 are assessed globally.

27

## 1 **2. Materials and Method**

### 2 **2.1 Climatic and socioeconomic scenarios**

3 Climate projections are based on ensemble runs (r1i1p1) by 13 models from  
4 CMIP5 (Table 1), covering the period 1976-2100 under three RCPs (i.e., RCP 2.6, 4.5,  
5 and 8.5).

6 Ten climate variables were used in this study. Specifically, 9 out of the 10 variables  
7 were applied for the calculation of potential evapotranspiration (PET). These 9  
8 variables include: surface maximum, mean, and minimum air temperatures, surface  
9 wind speed, relative humidity, surface downwelling and upwelling longwave fluxes,  
10 surface downwelling and upwelling shortwave fluxes. The 10<sup>th</sup> variable is the  
11 precipitation. Then the calculated PET and GCM-simulated precipitation were  
12 employed to calculate drought indices. The PET was initially calculated at the daily  
13 scale. Then both the daily scale PET and precipitation were aggregated to the monthly  
14 scales, and bilinearly interpolated to a spatial resolution of  $1.0^{\circ} \times 1.0^{\circ}$  on latitude and  
15 longitude for each model simulation.

16 To assess the exposures of populations and assets to droughts, which will  
17 eventually lead to higher drought losses in the future, instead of using a static  
18 socioeconomic scenario as many studies have (e.g., Hirabayashi et al., 2013; Smirnov  
19 et al., 2016), we employ the spatially explicit global shared socioeconomic pathways  
20 (SSPs). This dataset includes gridded population and GDP data under five SSPs,  
21 covering the period 2010-2100 at a spatial resolution of  $0.5^{\circ} \times 0.5^{\circ}$  (Jiang et al., 2017;  
22 2018; Su et al., 2018; Huang et al., 2019). It involves a sustainable scenario (SSP1), a  
23 pathway of continuing historical trend (SSP2), a strongly fragmented world (SSP3), a  
24 highly unequal world (SSP4), and a growth-oriented world (SSP5). Among  
25 combinations of different RCP trajectories and socioeconomic pathways, some SSP-  
26 RCP combinations are unlikely to occur, e.g., SSP3-RCP2.6 and SSP1-RCP8.5 (Jones  
27 et al., 2016). Considering the socioeconomic challenges for mitigation along different

1 development paths, the RCP2.6 scenario is associated with SSP1 (SSP126), which will  
2 face a lower challenge of mitigation in the future. The RCP4.5 scenario is associated  
3 with the SSP2 (SSP245), while the highest emission scenario RCP 8.5 is associated  
4 with the SSP5 (SSP585), by which a relatively higher challenge is expected under  
5 foreseeable warming conditions (Samir et al., 2017).

## 6 **2.2. Definition of a baseline, 1.5°C and 2°C global warming**

7 The sensitivity of annual global temperature to climate variability significantly  
8 varies in models and RCPs. Therefore, the time period with additional global warming  
9 of 1.5°C and 2°C with respect to pre-industrial conditions also varies between different  
10 climate scenarios. Here, the time periods for different global warming levels are  
11 determined using the 30-year running-mean of multi-model ensemble mean of global-  
12 mean surface air temperature, following previous studies (Vautard et al., 2014; Su et al.,  
13 2018). We first select a baseline period of 1976-2005, during which the observed global  
14 average temperature was approximately 0.46-0.66°C warmer than pre-industrial  
15 condition (IPCC, 2018). This reference period is widely adopted for climate impact  
16 assessment (e.g., Vautard et al., 2014), and we set the warming degree during baseline  
17 period as 0.51°C; hence the 1.5°C and 2.0°C warming targets are determined by  
18 additional warming of 0.99°C and 1.49°C, respectively. For each RCP, we define the  
19 1.5°C and 2°C warmer worlds by using the multi-model ensemble mean of global  
20 temperature. In other words, the reaching year is the same for all 13 GCMs under a  
21 specific RCP scenario and is determined as the 30-year period with mean temperature  
22 closest to the warming target for each RCP. (see Fig. 1).

## 23 **2.3 Drought indices and event identification**

### 24 **2.3.1 Standardized Precipitation Evapotranspiration Index**

25 The drought condition is quantified with the SPEI developed by Vicente et al.  
26 (2010), which has been widely adopted in characterizing drought conditions (e.g.,  
27 Ayantobo et al., 2018; Wen et al., 2018). The SPEI quantifies the extent of atmospheric

1 water surplus and deficit relative to the long-term average condition by standardizing  
 2 the difference between precipitation and potential evapotranspiration (PET). The SPEI  
 3 with 3-month time scale (SPEI-3) is used in this study because it captures well the  
 4 shallow soil moisture available to crops and reflects seasonal water loss processes (Yu  
 5 et al., 2014).

6 The PET is first calculated using the Penman-Monteith approach suggested by the  
 7 Food and Agriculture Organization of the United Nations (FAO) (Allen et al., 1998):

$$8 \quad PET = \frac{0.408\Delta(R_n - G) + \gamma \frac{900}{t_{mean} + 273} u_2 (e_s - e_a)}{\Delta + \gamma(1 + 0.34u_2)} \quad (1)$$

9 where  $\Delta$  is the slope of saturation vapor pressure vs. air temperature curve (kPa  
 10 /°C) and is calculated by:

$$11 \quad \Delta = 4098 \times \frac{0.6108 \times e^{\frac{17.27 \times t_{mean}}{t_{mean} + 237.3}}}{t_{mean} + 237.3} \quad (2)$$

12 where  $t_{mean}$  is the surface mean air temperature (°C).  $R_n$  is the net radiation  
 13 (MJ/m<sup>2</sup>/day) and is calculated by:

$$14 \quad R_n = [rsds - rsus - (rlus - rlds)] * 10^6 * 3600 * 24 \quad (3)$$

15 where  $rsds$  and  $rsus$  ( $rlds$  and  $rlus$ ) are surface downwelling and upwelling  
 16 shortwave flux (surface downwelling and upwelling longwave flux), respectively  
 17 (w/m<sup>2</sup>).  $G$  is the soil heat flux (MJ/m<sup>2</sup>/day) and is close to zero at the daily scale.  $\gamma$  is  
 18 psychometric constant (kPa/°C) and is calculated by:

$$19 \quad \gamma = 0.665 \times 10^{-3} \times P \quad (4)$$

20 where  $P$  is the atmospheric pressure (kPa).  $u_2$  is the wind speed at 2m height (m/s),  
 21 transferred from:

$$22 \quad u_2 = 4.87 \times u_{10} / \ln(67.8 \times 10 - 5.42) \quad (5)$$

23 where  $u_{10}$  is the surface wind speed at the 10m height simulated by GCMs.  $e_s$  and  
 24  $e_a$  are saturation and actual vapor pressure (kPa), respectively:

1 
$$e_s = 0.6108 \times e^{\frac{17.27 \times tmp}{tmp + 237.3}} \quad (6)$$

2 
$$e_a = \frac{rhs}{100} \times e_s \quad (7)$$

3 where *rhs* is the relative humidity (%), and *tmp* is temperature (i.e., daily maximum  
4 and minimum air temperature). Due to the non-linearity of eq. (6), it would be more  
5 appropriate to apply the average saturated vapor pressure derived from the daily  
6 maximum and minimum air temperature.

7 The widely used Log-logistic distribution is employed for fitting the 3-month  
8 deficit of precipitation and PET (P-PET) (Touma et al., 2015):

9 
$$F(x) = [1 + (\frac{\alpha}{x - \lambda})^\beta]^{-1} \quad (8)$$

10 where,  $F(x)$  denotes the cumulative distribution function;  $\alpha$ ,  $\beta$  and  $\lambda$  represent shape,  
11 scale and location parameters, which are estimated by the maximum likelihood method  
12 (Ahmad et al., 1988).

13 The SPEI-3 can then be derived by standardizing the  $F(x)$  into a standard normal  
14 function with a transforming function  $\Phi^{-1}$  as follows:

15 
$$SPEI_{-3}(x) = \Phi^{-1}(F(x)) \quad (9)$$

### 16 **2.3.2 Drought event identification**

17 After calculating the SPEI-3 for global terrestrial grid cells, we derive the drought  
18 duration, intensity, and severity using the run theory for the reference and the 1.5°C and  
19 2°C warmer worlds. The run theory proposed by Yevjevich et al. (1967) is a useful and  
20 objective method for drought event identification, where a run represents a subset of  
21 time series, in which SPEI-3 is either beneath (i.e., negative run) or over (i.e., positive  
22 run) a fixed threshold. A run with SPEI-3 that continuously stays below -0.5 is defined  
23 as a drought event (Mishra et al., 2010; Zargar et al., 2011), which generally includes  
24 drought characteristics of duration and severity. The persistent time period during a  
25 drought event is further defined as the drought duration, while drought severity  
26 (dimensionless) is defined as a cumulative deficit below -0.5.

## 1 2.4 Bivariate return period and most likely realization method

2 Previous studies usually independently examined the change either in drought  
 3 duration or severity under climate warming, neglecting the multiplex nature of droughts  
 4 (Naumann et al., 2018). This study jointly models drought duration ( $D$ ) and severity ( $S$ )  
 5 via the copula function, which is versatile for describing dependent hydrological  
 6 variables due to its good flexibility of marginal distributions. The widely-used Gamma  
 7 distribution was adopted for fitting drought variables in each grid over the globe, and  
 8 we selected the Gumbel Copula to model the joint distribution of drought duration and  
 9 severity. Within the copula-based approaches, different definitions of joint return  
 10 periods (JRPs) have been proposed, such as OR, AND, Kendall, dynamic, structure-  
 11 based return periods (Yin et al., 2019). Among these, the OR case ( $T_{or}$ ) is usually  
 12 adopted in drought occurrence assessment (Zhang et al., 2015):

$$13 \quad T_{or} = \frac{E_l}{1 - F(d, s)} = \frac{E_l}{1 - C[F_D(d), F_S(s)]} \quad (10)$$

14 where,  $E_l$  represents the expected inter-arrival time of drought events, the joint  
 15 distribution  $F(d, s)$  could be described by a copula function  $C[F_D(d), F_S(s)]$ ;  $F_D(d)$  and  
 16  $F_S(s)$  indicate the marginal distribution functions of  $D$  and  $S$ , respectively.

17 Under the bivariate framework, the choice of an appropriate  $T_{or}$  leads to infinite  
 18 combinations of drought duration and severity. The drought events along the  $T_{or}$ -level  
 19 curve are generally not equivalent in terms of environmental and societal consequences,  
 20 and hence the likelihood of each event must be taken into consideration when selecting  
 21 appropriate joint quantiles. In this paper, the most likely realization method (Salvadori  
 22 et al., 2011; Yin et al., 2019) is used to choose the drought scenario with the highest  
 23 likelihood along the  $T_{or}$ -level isoline. For a given  $T_{or}$ , the most likely combination point  
 24 among all possible events can be derived by the following formula (Gräler et al., 2013):

$$25 \quad \left\{ \begin{array}{l} (d^*, s^*) = \arg \max f(d, s) = c[F_D(d), F_S(s)]f_D(d)f_S(s) \\ C(F_D(d), F_S(s)) = 1 - E_l / T_{or} \end{array} \right\} \quad (11)$$

26 where,  $f(d, s)$  represents the joint probability density function of drought duration

1 and severity,  $c[F_D(d), F_S(s)] = dC(F_D(d), F_S(s)) / d(f_D(d))d(f_S(s))$  indicates the density  
2 function of copula;  $f_D(d)$  and  $f_S(s)$  are probability density functions of drought  
3 duration and severity, respectively. Due to the complexity of deriving analytical  
4 solutions in Eq. (11), the harmonic mean Newton's method (Yin et al., 2018a) is applied  
5 to estimate the most likely realizations.

## 6 **2.5 Calculation of socioeconomic exposure under warmer condition**

7 To calculate the socioeconomic exposures by droughts in different warming  
8 environments, we evaluate the change of drought occurrence frequency in a bivariate  
9 context. Firstly, we estimate the bivariate quantiles of drought duration and severity  
10 (i.e., most likely realization) under one given JRP during the historical period. As the  
11 50-year drought events usually gained great attention by the scientific community and  
12 socio-climatic policymakers (Zhang et al. 2015; Naumann et al., 2018), we adopt this  
13 level as a reference for assessing possible drought implications. With the historical 50-  
14 year bivariate quantiles, we can recalculate the joint occurrence frequency under future  
15 additional 1.5°C and 2.0°C warming conditions, respectively. It can be inferred that  
16 areas with a JRP lower than 50 years are projected to suffer from more severe drought  
17 conditions. To explicitly assess the drought risk changes from 1.5°C to 2.0°C warming  
18 climates, we estimate the ratio of the recalculated recurrence frequency between these  
19 two warming periods. Taking the 50-year drought events as an example, we first  
20 determine the magnitudes (duration and severity) of the 50-year drought events in the  
21 historical period. Then we input the determined magnitudes of the 50-year drought  
22 events into the future joint distribution functions, recalculate the joint recurrence  
23 frequencies and convert them into new return period at the 1.5°C and 2.0°C warming  
24 climates. The ratio is then calculated by dividing the new return period in the 2.0°C  
25 warming future by the new return period in the 1.5°C warming. A ratio less than 1.0  
26 suggests that the new return period in 2.0°C warming climates further reduces compared  
27 to that in 1.5°C warming level, which means that reference drought events are more

1 common under the 0.5°C warming impacts and implies worrisome conditions.

2 To evaluate socioeconomic implications of drought with additional warming, we  
3 record the population and GDP in those areas with more severe drought conditions and  
4 define them as exposures by increasing drought risks. As previously stated, we consider  
5 the dynamic nature of socioeconomic development pathways by employing different  
6 SSPs, and used the multi-year average populations and GDPs during 30-year periods  
7 determined by different warming levels. After estimating the socioeconomic exposures  
8 for each GCM simulation, we use the multi-model ensemble mean as an indication for  
9 each grid cell to reduce model bias. Note that we select three RCPs and corresponding  
10 SSPs under two warming targets so that the analysis is performed on six scenarios.

### 11 **3. Results**

#### 12 **3.1 Projected changes in dryness**

13 We first examine changes in the mean and standard deviation of SPEI-3 from the  
14 historical reference period (1976-2005) to the 1.5°C warmer worlds (Fig. 2), indicated  
15 by the multi-model ensemble mean results. We find that mean SPEI-3 decreases at the  
16 global scale (across 85% of the land areas, excluding Antarctica), except in very limited  
17 regions at high-latitude areas (e.g., Siberia in Russia) where it exhibits a slight increase.  
18 The descending changes in the mean SPEI-3 imply that, over the majority of the globe,  
19 the probability distribution function of SPEI-3 would shift towards lower values and  
20 hence more severe dryness. Particularly, dramatic decreases combined with strong  
21 model agreement (in terms of sign of change) are presented in Southern America,  
22 Australia, and Northern Africa. This may be attributed to higher evaporative demands  
23 and more frequent and persistent dry spells associated with rising temperatures  
24 (Naumann et al., 2018). On the other hand, we also observe an increase in the standard  
25 deviation of SPEI-3 with additional 1.5°C warming, particularly in Northern Africa and  
26 Southwestern Asia. As the SPEI-3 follows the standard normal distribution, the  
27 increasing standard deviation means more variability in dryness, which hinders  
28 resilience efforts in a 1.5°C warmer world. These changes are consistent under three

1 different RCPs, indicating the robustness of this globally drier future.

2 How would the dryness pattern change from 1.5°C to 2.0°C warming climates? A  
3 progressive descending change in mean values of SPEI-3 is observed across 58% of the  
4 land surface with the global mean temperature increasing between 1.5°C and 2.0°C,  
5 although several high-latitude regions (i.e., Russia, Canada) show an insignificant  
6 opposite change (Fig. 3). This may be mechanically explained by thick clouds in these  
7 regions that strengthen the reflectance of shortwave radiation and limit the increase of  
8 latent heat flux as well as evapotranspiration, thus contributing to the mitigation of  
9 atmospheric aridity (Huang et al., 2017). For the change in the standard deviation of  
10 SPEI-3, we find that increases occur over continental regions almost globally,  
11 accompanied by minor spatial variability. Overall, the climatic metric SPEI-3 shows a  
12 strong negative response to the warming climate, suggesting that dryness will intensify  
13 in a future warming world.

### 14 **3.2 Projected changes in drought characteristics**

15 Fig. 4 shows the relative change of global drought duration and severity derived  
16 from SPEI-3 in the 1.5°C warmer world relative to the historical period under three  
17 different RCPs. The drought duration is projected to slowly prolong with warming  
18 across 78% of the land surface, and 44% of land areas has an increase of higher than  
19 10%, although the change is not significant in Russia and Sahel areas. The drought  
20 severity shows a much more pronounced rise globally, with significant increases  
21 (exceeding 50%) over 46% of global landmasses. Moreover, several regions experience  
22 compound increases (with strong model agreement) in both drought severity and  
23 duration, such as Southeast Asia, Mediterranean, Southern Africa, Southern North  
24 America, and South America, suggesting an urgent need to increase societal and  
25 environmental resilience to a warming climate there. In the tropics and high-latitudes  
26 areas, the drought severity is projected to increase while the duration will decrease. In  
27 these regions, mitigation strategies should target short, intense bursts of drought.

28 When the global temperature rises from additional 1.5°C to 2.0°C warming, the  
29 world would experience more severe drought conditions, with a further increase in

1 drought severity accounting for 75% of the land surface (differences in effects between  
2 the 1.5°C and 2.0°C warming levels) and a persistent lengthen in duration across 58%  
3 of the land areas (Fig. 5). Similar to the changing pattern from baseline to a 1.5°C  
4 warming climate, the drought severity shows a more rapidly increasing rate than  
5 drought duration globally under the 2.0°C warming world. Comparing the 2.0°C to the  
6 1.5°C warming condition, the increase in drought severity is greater than 10% over 35%  
7 of the land areas, while only 8% of the land areas show such an increase (>10%) in  
8 drought duration. This drought-prone condition is more severe in several regions such  
9 as Mediterranean regions, South Africa and South America, posing large challenges for  
10 existing socio-hydrological systems there.

11 To explicitly investigate the changes of drought characteristics under warming  
12 conditions, we also show statistics of drought frequency, duration and severity in the  
13 historical period and future additional warmer worlds in violin plots (Fig. 6), in which  
14 the distributions comprise drought characteristics across all land pixels of the multi-  
15 model ensemble mean results. The violin plots (Hintze et al., 1998) consist of a boxplot  
16 inside and an outside violin shape which displays the probability distribution of drought  
17 characteristics. Apparently, the drought frequency based on SPEI-3 is also projected to  
18 pronouncedly lengthen under three RCPs, accompanied by large variability capturing  
19 by the kernel density estimation in Fig 6. This rapid increasing tendency also holds true  
20 for drought duration and severity, and extreme conditions are projected to occur more  
21 frequently under warming climates. For example, the 90% uncertainty range of drought  
22 duration (severity) increases from 2.2-6.5 months to 1.8-7.8 months (from 2.1-6.6 to  
23 2.0-12) under 2.0°C warming climate relative to the historical period.

### 24 **3.3 Projected changes in drought risks**

25 As evidence is accumulating that high-impact events are typically multivariate in  
26 nature (Zhang et al. 2015; Ayantobo et al., 2017), we now consider a deeper focus on  
27 changes in drought severity and duration within a bivariate framework under different  
28 warming levels. Using the copula-based approach in Section 2.4, we show the median  
29 projected change of the historical 50-year drought conditions over multi-model

1 ensembles under 1.5°C warming climate (Fig. 7). Generally, in regions with a  
2 substantial increase in drought duration and severity (Fig. 5), the 50-year drought events  
3 exhibit a rapid increase in occurrence with warming. More than 88% of global  
4 landmasses will be subject to more frequent historical 50-year droughts, and the  
5 frequency of such severe droughts would double over 58% of the global land surface.  
6 For most areas of South America (except for the zone around the equator), Northeastern  
7 America, Central, and West Asia, and northwest China, the historical 50-year droughts  
8 are projected to occur 2 to 10 times more frequently under the ambitious 1.5°C warming  
9 level. Regions with a lower frequency of historical 50-year drought event indicate a  
10 reduction in drought risks, which are only limited in Siberia, India Peninsula, and  
11 Alaska.

12 To closely assess the drought conditions with an extra 0.5°C warming, we derive  
13 the ratio of adjusted 50-year return period between 2.0°C and 1.5°C warming worlds  
14 (Fig. 8). In regions with a ratio of less than 1.0, the present drought events are projected  
15 to occur more frequently under the half a degree additional warming, which accounts  
16 for 71% of continental areas. In addition, the frequency of the historical 50-year  
17 droughts would double across 67% of the global landmasses under the 2.0°C warming  
18 level. That is, 9% increase of the world land areas compares to the 1.5°C warming level  
19 (i.e., 58%). Although over some regions such as northern Canada and Eastern Asia, the  
20 occurrence of the extreme droughts will be less frequent to some degree, strong rises in  
21 recurrence frequency with warming are projected to dominate large parts of Europe, the  
22 southern United States, Australia, South America, Northern Africa, and the  
23 Mediterranean.

### 24 **3.4 Population and GDP exposure from increasing drought risks**

25 To understand the socio-economic influences induced by increasing drought risks  
26 (here defined as more frequent historical 50-year events), we combine the drought  
27 projection with population and GDP information based on SSPs, and estimate  
28 exposures by droughts in the 1.5°C and 2.0°C warmer worlds. Here, instead of using  
29 the absolute value of population (and GDP) to assess the nation-wide drought exposures,

1 the nation-wide population (and GDP) fraction is employed. This can avoid covering  
2 up badly drought-affected countries where the national population (or GDP) are small  
3 (or low) regarding the world level. Specifically, for a country (e.g., the United States),  
4 the fraction of drought-affected population (and GDP) divided by the total population  
5 (and GDP) of this country is employed as the indicator. Therefore, the most drought-  
6 affected countries are presented by high fractions. Globally, three SSPs suggest a  
7 consistent projection that large percentages of population and GDP will be exposed to  
8 increasing drought risks. In more than 67 (140) countries, 100% (50%) of both  
9 populations and GDPs are exposed to more severe droughts under the 1.5°C warming  
10 target (Fig. 9). The two socioeconomic factors of GDP and population are highly  
11 correlated (O'Neill et al., 2014). Economically prosperous regions are associated with  
12 higher population and immigration (Fig. S1); thus the drought-affected GDP exposures  
13 usually exhibit similar changing pattern with the population. In regions with low GDP  
14 and population density, even when total socioeconomic exposures to droughts seem  
15 small, droughts can still cause fatal and destructive losses for those countries if their  
16 drought resilience is poor. To give a fairer and more impartial assessment of droughts'  
17 socioeconomic consequences, we define and assess the fraction of drought-affected  
18 population (or GDP) divided by total national population (or total GDP) based on  
19 different countries in a 1.5°C warming world. In addition, we see some interesting  
20 results. For example, the United States and China are no longer the most drought-  
21 affected countries, while 100% of the population and GDP in Mexico, Southern Europe,  
22 Middle, and Southern Africa, and Mediterranean regions (i.e., Turkey, Ukraine) are  
23 projected to experience more severe drought, suggesting large policy challenges there.

24 To illustrate the consequences of limiting warming to 2.0°C above the preindustrial  
25 levels, we also calculate the socioeconomic exposures under three SSPs (Fig. 10) and  
26 the differences in percentage between the 1.5°C and 2.0°C warming levels (Fig. S2).  
27 Most regions of the globe are projected to exhibit a generally increasing fraction  
28 (relative to 1.5°C warming) in populations and GDPs (except for Central Africa and  
29 East Asia). To be specific, under the extra half-degree warming, an additional 17

1 countries are projected to exhibit a 100% fraction in socioeconomic exposure. More  
2 than 10 countries would experience a 30% increase in population and GDP exposure if  
3 the global warming level increased from 1.5°C to 2.0°C. These increases illustrate the  
4 benefit of holding global warming to 1.5°C instead of 2°C, particularly for the  
5 mitigation of population and GDP exposure to drought. It should be noted that when  
6 climate warming climbing from 1.5°C to 2.0°C, there are some spatial heterogeneity  
7 with regards to drought exposures variations. Specifically, drought exposures for some  
8 countries (i.e., Canada) can be slightly decreased in 2°C warming level compared to  
9 1.5°C warming level. This decrease in population and GDP exposure fraction can be  
10 attributed to the decreasing land fraction exposing to more frequent droughts (Table S2).  
11 For example, the land fraction suffering more frequent severe droughts in Canada will  
12 decrease (-12.77%) in 2.0°C warming level comparing to 1.5°C warming under SSP126  
13 scenario. In other words, the additional 0.5°C warming will not lead to drought risk  
14 deterioration globally, partly due to the increasing column precipitable water with  
15 warming environment (Dong et al., 2019; Yin et al., 2019b), although it holds for the  
16 majority of global land masses. Anyway, the spatial heterogeneity should be paid  
17 attention especially when assessing the climate change impacts on extreme events at  
18 regional or local scales (Liu et al., 2018b).

### 19 **3.5 National assessment of socioeconomic exposure in typical countries**

20 The large spatial variability of drought risks and socioeconomic exposures under  
21 climate warming motivates a more systematic and in-depth assessment on national  
22 scales, particularly for the countries vulnerable to droughts. Therefore, we investigate  
23 more thoroughly the drought-affected land fractions (Figs. 11-12) and corresponding  
24 socioeconomic exposure (Figs. S3-4) in eight hotspot countries spanning different  
25 socio-climatic regions: Argentina, Australia, Canada, China, United States, South  
26 Africa, Brazil, and Mexico.

27 For assessment at the national scale, spatially aggregating mean changes are more  
28 helpful than per-grid cell changes to indicate the risk of a particular land fraction being  
29 impacted by climate change (Fischer et al., 2013; Lehner et al., 2017). The land

1 fractions of each grid cell are binned and plotted against the change of drought return  
2 period (relative to historical 50-year drought) (Figs. 11-12). The bin number is fixed to  
3 20 groups for the eight example countries. In a 1.5°C warming world (Fig. 11), these  
4 spatially aggregated changes explicitly show a significant increase in drought risks over  
5 these hotspot countries, with more than 90% of grid cells projected to suffer from more  
6 frequent droughts.

7        Nevertheless, we still observe a difference between the tropics and extratropical  
8 regions. The increasing drought risks are more profound in tropical regions (e.g.,  
9 Mexico and Brazil) than those over the high-latitude country (e.g., Canada). For  
10 instance, in a 1.5°C warming world, more than 85% of the grid cells (associated with  
11 around 65%-97% of the national populations and GDPs) over Mexico and Brazil could  
12 be exposed to the historical 50-year drought every 20 years. This pronounced increase  
13 in drought risks over tropical countries may be attributed to an oceanic forcing that  
14 favors the formation of deep convection over the ocean and thus weakened the  
15 continental convergence associated with the monsoon (Giannini et al., 2013). This  
16 finding suggests that the tropics may confront more severe, frequent droughts and worse  
17 socioeconomic influences (Figs. S3-4) under a warming climate. When the additional  
18 warming target rises up to 2.0°C, drought conditions worsen over all these example  
19 countries (Fig. 12). The increase in drought risks is still more pronounced in the tropical  
20 countries. More than 90% of the grid cells (associated with around 90%-100% of the  
21 national population and GDP) across Brazil and Mexico will experience drought  
22 frequency double that of the historical 50-year drought.

23        Overall, increasing drought risks under warming climates can cause major  
24 challenges for sustainable development and existing infrastructure systems, while  
25 ambitiously limiting warming to 1.5°C would substantially mitigate future drought risks  
26 and corresponding socioeconomic exposures.

## 27 **4. Discussion**

28        Among the warming-induced hydrological changes, one of the most definitive and

1 detectable changes is the simultaneous increase of precipitation and evaporative  
2 demand, which are governed by the Clausius-Clapeyron relationship (Scheff et al.,  
3 2014). Observations and model simulations have reported a variety of scaling rates  
4 between precipitation and global temperature, where the daily and hourly precipitation  
5 extremes (i.e., 99<sup>th</sup> / 95<sup>th</sup> percentile precipitation) usually exhibit a sub C-C scaling at  
6 regional scales, accompanied by spatial and decadal variability (Yin et al. 2018b). For  
7 global average precipitation, however, most climate models project an increase of 1-3%  
8 per degree warming (Liu et al., 2013). This deviation from the C-C relation law is due  
9 to a global radiative energy constraint (Held et al., 2006) and atmospheric moisture  
10 limitation by decreasing relative humidity and increasing the potential for intense  
11 tropical and subtropical thunderstorms under warming (Muller et al., 2011; Yin et al.  
12 2018b). Potential evapotranspiration, on the other hand, is predicted to increase by 1.5-  
13 4% per degree warming (Scheff et al., 2014; Naumann et al., 2018). Therefore, we  
14 expect climate warming to lead to a general intensification of drought conditions, as the  
15 drying of the surface is enhanced with water scarcity. This is confirmed by the  
16 decreasing SPEI-3 and significantly increasing drought severity and duration with  
17 warming globally found here (Figs. 2-8).

18 The reference crop Penman-Monteith model is employed to calculate potential  
19 evapotranspiration (and thus SPEI) in the current study. In this process, surface  
20 resistance ( $r_s$ ) is fixed to 70 s/m. However, according to recent studies (e.g., Roderick  
21 et al., 2015; Yang et al., 2018), an elevated CO<sub>2</sub> environment can drive stomatal closure,  
22 increasing stomatal resistance and further increasing  $r_s$ . Subsequently, this increasing  $r_s$   
23 causes the decline in the potential evapotranspiration, especially across vegetated lands  
24 where the photo-synthetic rate is high. From this perspective, the neglect of increasing  
25  $r_s$  may overestimate future drying condition and corresponding drought risk changes to  
26 some extent. However, on the other hand, the increase in total leaf area with CO<sub>2</sub> and  
27 growing-season length can cause countervailing decreases in  $r_s$  (Greve et al., 2019).  
28 Overall, accurate and robust quantification of  $r_s$  scaling with CO<sub>2</sub> still needs  
29 additionally explicit work and substantial observed data. Though the impact of  $r_s$  on the

1 drought assessments deserves further studies, it is beyond the scope of this study.  
2 Therefore, the traditional fixed  $r_s$  method is used in this study to calculate potential  
3 evapotranspiration.

4 In the run theory, once the threshold (e.g., -0.5) is determined, drought events with  
5 different severity magnitudes are identified and constitute a sample for the selected time  
6 period. This sample contains different magnitudes in severity and different lengths in  
7 the duration, therefore, characterizes the distribution of different levels of drought  
8 (ranging from the mild, moderate to extreme conditions). On the other hand, different  
9 threshold values in identifying a drought event may cause disparities regarding drought  
10 risk changes and may challenge the robustness of our results. Generally, the threshold  
11 value usually ranges between -1 and 0 (Xu et al., 2015; Ayantobo et al., 2017, 2018;  
12 Yuan et al., 2017; Jiao et al., 2019). Herein, the threshold of -0.5 is employed to identify  
13 droughts varying from mild to extremely dry levels (Table 2, Chen et al., 2018), which  
14 has been widely adopted in drought-related studies (Liu et al., 2015; Xiao et al., 2017;  
15 Chen et al., 2018). The inclusion of minor drought events can enlarge the sample size  
16 in bivariate frequency analysis and thus circumvents the problem of insufficient  
17 samples. Moreover, to verify the robustness of our results, we also use the -0.8 threshold  
18 to serve as a comparison. Relevant results are shown in Figs. 13-15. Fig.13 displays  
19 comparisons of distributions comprising drought characteristics (i.e. drought frequency,  
20 drought duration and drought severity) across all land pixels between using the -0.8 and  
21 -0.5 as the threshold. Figs. 14-15 show comparisons of projected changes in joint 50-  
22 year return periods of droughts between using the -0.8 and -0.5 as the threshold under  
23 different warming levels. As shown in the figure (Fig.13), drought characteristics tend  
24 to slightly decrease across different periods. However, future drought risk changes as  
25 indicated by the 50-year joint return period deriving from the -0.8 threshold are similar  
26 to those from the -0.5 threshold (Figs. 14-15). In addition, we also derive changes in  
27 drought risks for the 20-year or 100-year drought events to explore risk variations  
28 caused by different extents of drought (Figs. S5-6). Results shows that although the  
29 magnitudes of changes are different, they present quite similar spatial patterns.

1 Furthermore, since the calculation of socioeconomic exposures to droughts is based on  
2 the variations of drought risks when employing the same dynamic population (and GDP)  
3 pathways, similar changes in the drought risks will lead to analogical socioeconomic  
4 exposures. As a reference, we analyze the socioeconomic exposures in the case when -  
5 0.8 is used as the threshold (Figs. S7-8). Compared with the results of the -0.5 threshold  
6 (Figs. 9-10), the overall characteristics of the drought exposures are mostly the same.  
7 This confirms the conclusions of our study.

8         Although aggravated drought risks are projected globally, the changing patterns  
9 exhibit large spatial variability, with more significant increases over mid-latitudes and  
10 tropical regions than those over high-latitude landmasses. It should be noticed that  
11 regions (e.g., the Mediterranean, Southern Africa, Southern North America) with large  
12 projected changes generally display strong model agreement (in terms of sign of  
13 change), which implies high confidence in these drought prone areas. Conversely,  
14 substantial model uncertainty of drought projections is particularly clear for regions  
15 with small changing amplitudes, as indicated by weak model agreement (e.g.,  
16 Southeastern Asia and Russia). For example, 100% of the population in tropical regions  
17 like Brazil and Mexico would be affected by increasing drought risks. Indeed, our  
18 finding that the tropical and mid-latitude regions, where the vast majority of global  
19 population resides, would bear the greatest drought risks should be precautionary under  
20 the foreseeable warming future. Previous studies have reported that the increases in El  
21 Niño frequency (Xie et al., 2010), an extension of Hadley cell (Lu et al., 2007), and  
22 poleward moisture transport by transient eddies (Chou et al., 2009) under warming all  
23 contribute to the drying tendency in tropics; however, our work does not quantitatively  
24 examine these underlying physical mechanisms behind the spatial variability due to  
25 paucity of data.

26         When investigating socioeconomic exposure (i.e., population and GDP) under  
27 different warming levels, we notice that drought risks and population (GDP) both  
28 contribute to the exposure change. However, the use of population and GDP for a single  
29 year (i.e. 2005 or 2100) which have been used by some earlier studies (e.g., Peters,

1 2016; Park et al., 2018; Liu et al. 2018a) have ignored the role of dynamic socio-  
2 economic impacts. This ignorance may lead to biased conclusions. In this study, the  
3 dynamic characteristics are considered as differences in population (and GDP) between  
4 the fixed 30-year 1.5°C and 2.0°C warming periods (Table 3). Accordingly, the  
5 exposure is defined as the number of people (GDP) being exposed to areas where the  
6 bivariate drought risks increase under the warming climate. At the 1.5°C warming  
7 climate, there are around 88% of global landmasses being exposed to increasing  
8 drought risks, which correspond to 1386.9 million population (and 33311.1 billion USD)  
9 according to the average of the three SSPs from a global perspective. At the 2.0°C  
10 warming level, though there are still 88% of the global land areas being exposed to  
11 increasing drought risks, the affected population (and GDP) will soar to 1538.2 million  
12 (and 72852.2 billion USD). In this light, the increase in population (and GDP)  
13 contributes to the increasing exposures. Therefore, it is important to incorporate the  
14 dynamic population (and GDP) into exposure calculating processes. Nevertheless,  
15 when further investigating the affected population (and GDP) between the two warming  
16 climates, the role of drought risk changes should also pay attention. Specifically, though  
17 the percentage of landmasses with increasing drought risks stay unchanged for both the  
18 1.5°C and 2.0°C warming climates (both approximately 88%), the magnitudes of risk  
19 changes are different. For instance, drought risks will double across around 58% of the  
20 global landmasses at the 1.5°C warming level, while the same drought risks will occur  
21 over 67% of the global landmasses at the 2.0°C warming level. Those differences in the  
22 magnitudes of drought risk changes can definitely bring about divergent impacts to  
23 local population and economy. Therefore, our study strengthens the benefits and  
24 necessity of controlling the global warming at 1.5°C level.

25 For a complete analysis of climate change impact assessment, it is important to  
26 know the role of corresponding uncertainty especially induced by Global Climate  
27 Models (GCMs) and RCP scenarios. Measured by the 90% range of the changing  
28 characteristics of SPEI-3 from historical to 1.5°C warming world and from 1.5°C to  
29 2.0°C warming target, the uncertainty induced by multi-model ensembles are quantified

1 in each grid under three RCPs (Figs. S9-10). Compared with the ensemble mean change  
2 of SPEI-3 shown in Figs. 2-3, we find that the model uncertainty is relatively large,  
3 particular for South America and Africa where the 90% range even exceeds the  
4 ensemble mean change. This finding also holds true when evaluating the drought  
5 duration and severity (Figs. S11-12), suggesting that model uncertainty cannot be  
6 ignored in climate change impact studies.

7 To fully consider model uncertainty on drought conditions, we also present the  
8 bivariate return period of the present 50-year drought condition for each model under  
9 RCP 4.5 in a 1.5°C warming world, and the occurrence change under an additional  
10 0.5°C warming (Figs. S13-14). As expected, different climate models show large  
11 variations, and several models even exhibit opposite changes over certain regions.  
12 Despite this uncertainty, most models still project general increasing risks at the global  
13 scale under climate warming, particularly for middle-latitude areas and tropics. For  
14 RCP uncertainty, although we notice that the three scenarios present similar variations  
15 to some extent, there are still discernable differences especially when the warming  
16 increasing from the 1.5°C to the 2.0°C warming level. Generally, the warming  
17 trajectories are dependent on RCP scenarios. In other words, different RCP scenarios  
18 correspond to various temperature levels for the fixed time period. However, this study  
19 fixed the warming level. It can be expected that the differences among RCP scenarios  
20 are largely reduced. Nevertheless, the complex circulation system can still result in  
21 some differences in hydro-meteorological variables (e.g., precipitation, wind speed and  
22 relative humidity) among RCP scenarios, even at the same warming level, because they  
23 are not linearly related to the warming temperature. Since drought conditions are  
24 evaluated by using such hydro-meteorological variables, those differences at the same  
25 warming level can lead to variations in drought evolutions. Furthermore, drought  
26 variations under three scenarios are even to some extent significant at the regional or  
27 national scales. For example, when the warming level increasing from 1.5°C to 2.0°C,  
28 the GDP exposure for the Colombia will decrease at the SSP126 scenario while it will  
29 increase at the SSP585. Future studies may explore their potential physical mechanisms

1 (i.e., connecting drought evolution with land-atmosphere interactions). For other  
2 uncertainty sources, several previous studies (Wang et al., 2018; Gu et al., 2019; Chen  
3 et al., 2019) have been devoted to detecting and attributing uncertainty to GCM  
4 structure, RCPs, internal climate variability, and even drought indices and so on. Here,  
5 it is challenging to consider all these uncertainties systematically; future work could  
6 focus on including the integrated uncertainty and quantifying relative contributions on  
7 drought evolution and impact assessments.

8 Finally, there are some extra issues need to pay attention. For instance, to fully  
9 consider the robustness of the results, we use the warming level of multi-model  
10 ensemble mean to serve as the warming trajectory. Firstly, comparing to the method of  
11 determining warming level by individual model output, the use of multi-model  
12 ensemble mean method involves more future projections/GCMs and thus guarantees  
13 the reliability of the conclusions (Chen et al., 2011; Mehran et al., 2014). This multi-  
14 model ensemble mean method is also consistent with some previous studies (Liu et al.,  
15 2018a, 2019; Su et al., 2018). Secondly, the application of the multi-model ensemble  
16 mean method keeps the consistency of the sample size under each RCP and for each  
17 warming level. This can exclude the differences originated from the sample size when  
18 assessing different warming level impacts or evaluating RCP uncertainty. It is true that  
19 different warming level calculating methods can result in divergent model ensembles  
20 and may thus affect the results. For example, some studies (Sanderson et al., 2017;  
21 Lehner et al., 2017) used single model to conduct climate warming impact assessments,  
22 while some studies (James et al., 2017; Thober et al., 2018) employed pooled future  
23 projections (i.e. 1.5/2.0°C) to perform analyses without considering RCP discrepancies.  
24 Future studies may explore the impacts of different warming level calculation methods,  
25 but it is beyond the scope of the current study.

26 In addition, considering the relative coarseness of the CMIP5 models, it may be  
27 more appropriate to re-grid the GCM outputs to a common rough grid (e.g., 2°).  
28 However, the spatial resolution of population and GDP used in this study is 0.5°×0.5°,  
29 which have to be upscaled to the same resolution of GCM outputs. But a coarse grid

1 may be larger than the largest city in the world, thus, it is inappropriate to reflect the  
2 regional population and GDP exposures. Besides, some national territory areas are  
3 small, a finer resolution (e.g.,  $1^\circ \times 1^\circ$ ) may be more appropriate to obtain reliable  
4 population and GDP exposure results at the national scale. The same spatial resolution  
5 has been used in other studies (e.g., Schneider et al., 2016; Li et al., 2018; Yang et al.,  
6 2019). Nevertheless, in order to validate the rationality of interpolation to  $1^\circ$  spatial  
7 resolution, we also re-gridded the data to  $2^\circ$  grid and further re-conducted our studies  
8 (Figs. S15-16). Overall, there are only slight differences between the results of  $1^\circ$  and  
9  $2^\circ$  resolution, confirming the reliability of our results.

10

## 11 **5. Conclusions**

12 Motivated by the 2015 Paris Agreement proposal, we quantify the changes in  
13 global drought bivariate magnitudes and socioeconomic consequences in the  $1.5^\circ\text{C}$  and  
14  $2.0^\circ\text{C}$  warmer worlds, with climate projected by the multi-model ensemble under three  
15 representative concentration pathways (RCP2.6, 4.5, and 8.5). The drought  
16 characteristics are identified using the SPEI combined with the run theory, and the  
17 changes in occurrence are measured by both drought duration and severity, with the  
18 incorporation of the copula functions and most likely realization method. The main  
19 conclusions are summarized as follows (Table S1):

20 (1) The mean of SPEI-3 from the historical period to the  $1.5^\circ\text{C}$  and  $2.0^\circ\text{C}$  warmer  
21 worlds are projected to descend at a global scale, while the standard deviation exhibits  
22 large increases. As the SPEI-3 following the normal distribution, these changes suggest  
23 that the distribution of SPEI-3 would shift towards the negative side with a flatter  
24 tendency, implying a more severe drying condition in a future warming world.

25 (2) The drought duration is projected to slowly prolong across 78% of the land  
26 surface, while the drought severity shows a much more pronounced rise globally in the  
27  $1.5^\circ\text{C}$  warming world. Compared to  $1.5^\circ\text{C}$  warming condition, there will be a further  
28 increase in drought severity and a persistent lengthening in drought duration under the

1 additional 2.0°C warming level. Several regions in middle-latitude regions and the  
2 tropics would experience substantial increases in drought magnitude, such as Southeast  
3 Asia, the Mediterranean, Southern Africa, Southern North America, and South America.

4 (3) More than 58% of global landmasses would be subject to twice more frequent  
5 historical 50-year droughts even under the ambitious 1.5°C mitigation target. The  
6 drought condition will further worsen under 2.0°C warming climate, with around a 9%  
7 increase of the world landmasses experiencing such severe deterioration comparing to  
8 the 1.5°C warming level.

9 (4) More than 75 (73) countries are projected to exhibit a 100% fraction in the  
10 population (GDP) exposed to increasing drought risks even under the ambitious 1.5°C  
11 warming trajectories. An extra 0.5°C warming will lead to an additional 17 countries  
12 exhibiting a 100% fraction in socioeconomic exposure. Moreover, tropical countries  
13 (i.e., Mexico and Brazil) will be subject to dramatically increased drought risks, with  
14 85% of the land fraction would experiencing a doubled frequency of severe historical  
15 droughts under the 1.5°C warming target; when the warming is increasing to 2.0°C, the  
16 corresponding land fraction is projected to approach 90%.

## 17 **Data availability**

18 The climate simulation data can be accessed from the CMIP5 archive ([https://esgf-](https://esgf-node.llnl.gov/projects/esgf-llnl/)  
19 [node.llnl.gov/projects/esgf-llnl/](https://esgf-node.llnl.gov/projects/esgf-llnl/)). The SSP data are provided by Prof. Buda Su and Prof.  
20 Tong Jiang in National Climate Center, China Meteorological Administration.

21

## 22 **Author contributions**

23 JC conceived the original idea, and LG designed the methodology. JC, LPZ and JSK  
24 collected the data. LG developed the code and performed the study, with some  
25 contributions from JC and HMW. LG, JC, JBY, SCS and SLG contributed to the  
26 interpretation of results. LG and JBY wrote the paper, and JC, SCS, SLG, LPZ and JSK  
27 revised the paper.

1

## 2 **Conflict of interest**

3 The authors declare that they have no conflict of interest with the work presented here.

4

## 5 **Acknowledgements**

6 This work was partially supported by the National Key Research and Development  
7 Program of China (No. 2017YFA0603704; 2016YFC0402206), the National Natural  
8 Science Foundation of China (Grant Nos. 51779176, 51539009, 51811540407), the  
9 Overseas Expertise Introduction Project for Discipline Innovation (111 Project) funded  
10 by Ministry of Education and State Administration of Foreign Experts Affairs P.R.  
11 China (Grant No. B18037), and the Thousand Youth Talents Plan from the Organization  
12 Department of CCP Central Committee (Wuhan University, China). The authors would  
13 like to thank the World Climate Research Program working group on Coupled  
14 Modelling, and all climate modeling institutions listed in Table 1 for making GCM  
15 outputs available. We also thank Prof. Buda Su and Prof. Tong Jiang in National  
16 Climate Center, China Meteorological Administration for sharing the SSP data.

33 0.5 as the threshold and the -0.8 as the threshold under the 1.5°C warming target

34 Fig. 15. Projected changes in joint 50-year return periods of droughts when using the -  
35 0.5 as the threshold and the -0.8 as the threshold between the 1.5°C and 2.0°C warming  
36 target

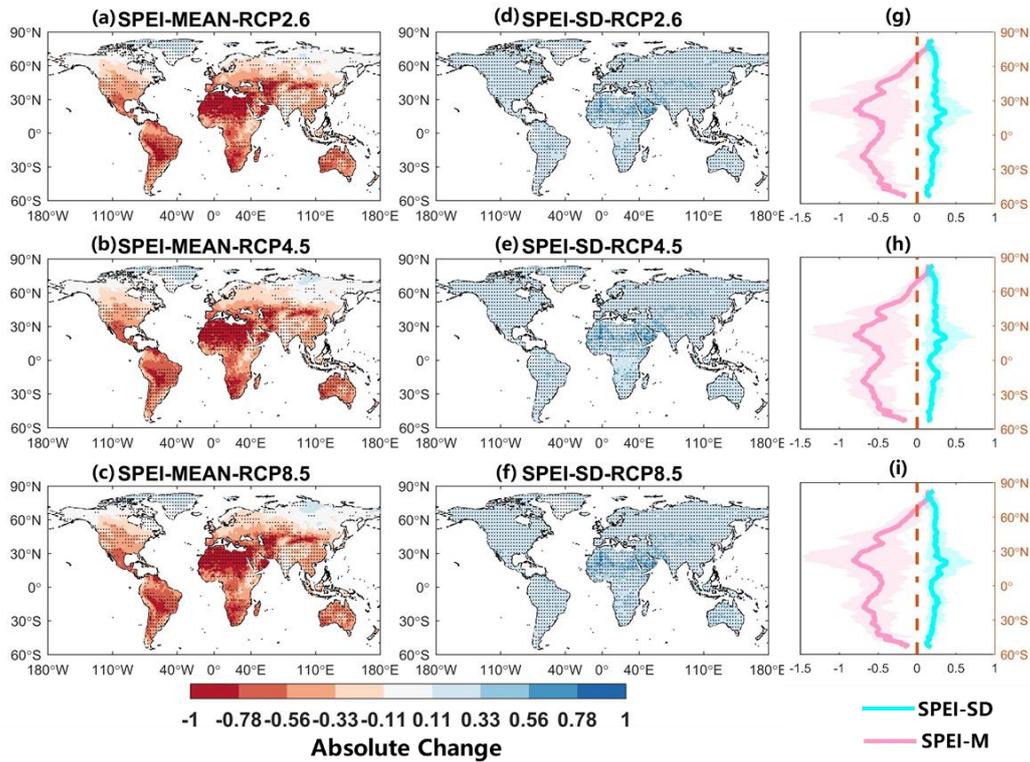

37

38

39 **Fig. 1. Projected global mean temperatures when reaching 1.5°C warming (a) and**  
 40 **2.0°C warming (b).**

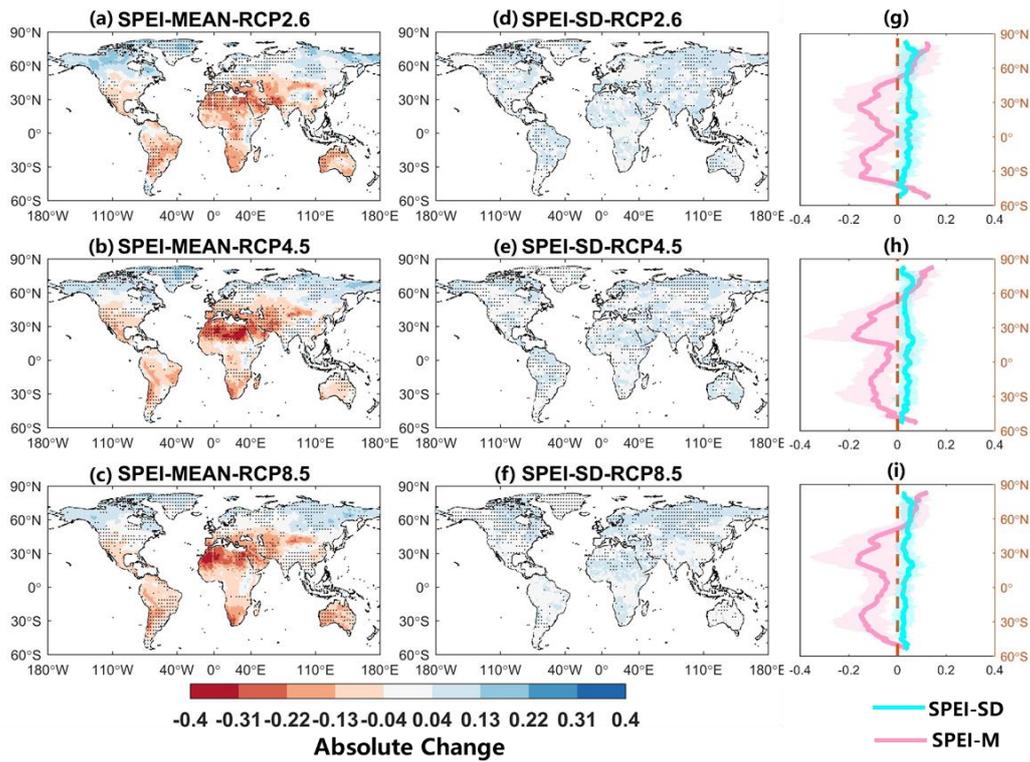

41 Development of centered 30-year global average temperatures for all 13 General  
 42 Circulation Models (GCMs) and 3 Representative Concentration Pathways (RCPs)  
 43 included in this study. The vertical dark lines mark the uncertainty when the warming  
 44 target is reached. In **Fig.1a**, the determined time in RCP2.6 is the same with that in  
 45 RCP4.5, so the vertical dashed grey line is covered by the dashed cyan line.

46

47 **Fig. 2. Projected changes in the mean and standard deviation of SPEI under the**  
 48 **1.5°C warming target**

49 Maps of the projected changes in the mean (a,c,e) and standard deviation (b,d,f) of  
 50 SPEI from historical reference period (1976-2005) to the 1.5°C warming target under  
 51 RCP2.6, RCP4.5, and RCP8.5. (g,h,i) Zonal results for changes in 1° latitude bin.  
 52 The stippling (a-f) is shaded for areas where at least 80% (i.e., 10 out of 13) of the  
 53 GCMs agree on the sign of the change.

54

55 **Fig. 3. Projected changes in the mean and standard deviation of SPEI between the**  
 56 **1.5°C and 2.0°C warming target**

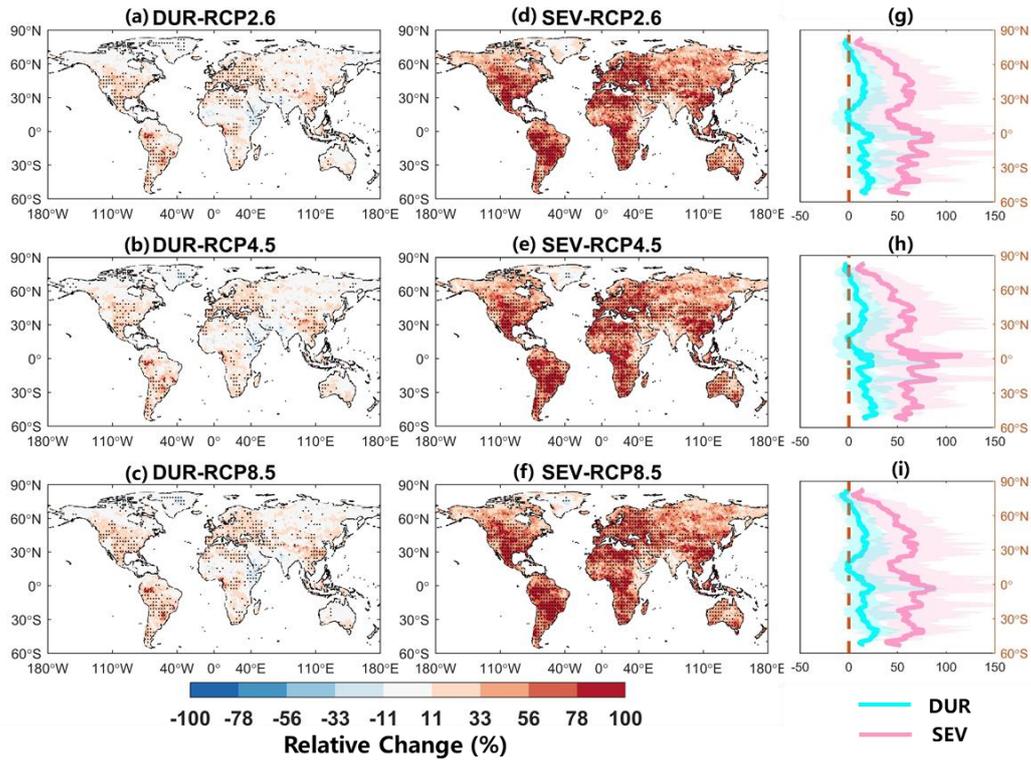

57 Maps of the projected changes in the mean (a,c,e) and standard deviation (b,d,f) of  
 58 SPEI from 1.5°C to the 2.0°C warming target under RCP2.6, RCP4.5, and RCP8.5.

59 (g,h,i) Zonal results for changes in 1° latitude bin. The stippling (a-f) is shaded for areas  
 60 where at least 80% (i.e., 10 out of 13) of the GCMs agree on the sign of the change.

61

62

63

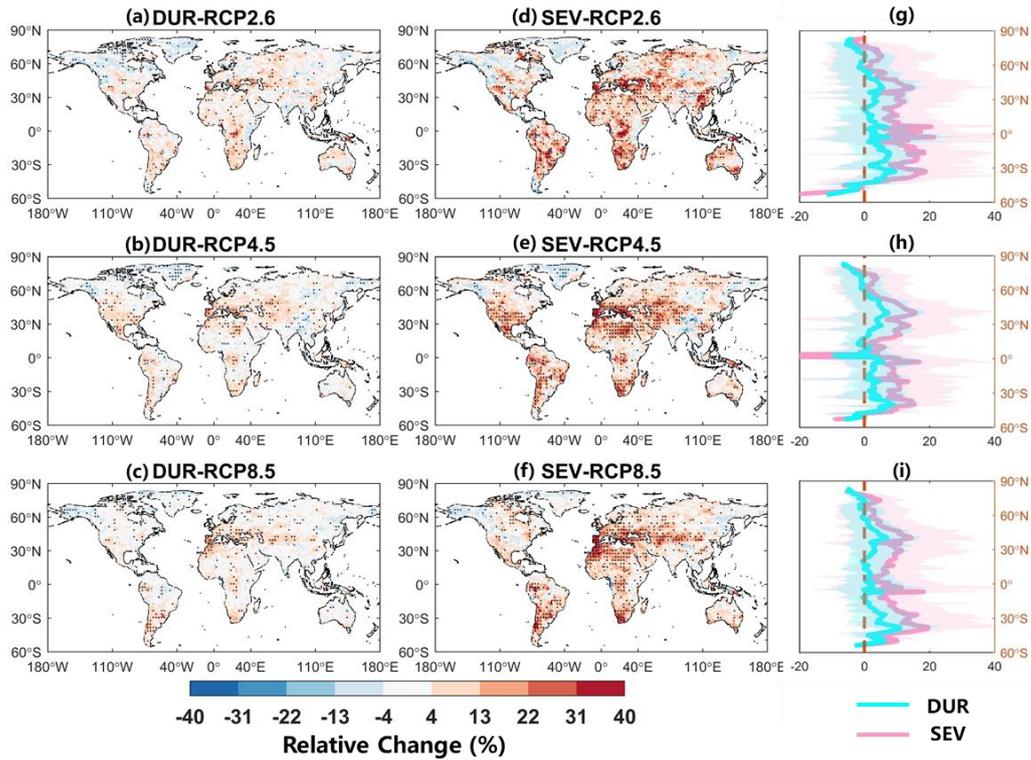

64

65 **Fig. 4. Projected changes in drought duration and severity under the 1.5°C**  
 66 **warming target**

67 Maps of the relative changes (%) in the multi-model ensemble mean drought duration  
 68 (a,c,e) and drought severity (b,d,f) from the reference period (1976-2005) to the 1.5°C  
 69 warming target under RCP2.6, RCP4.5, and RCP8.5. (g,h,i) Zonal results for drought  
 70 duration and severity in 1° latitude bin. The stippling (a-f) is shaded for areas where at  
 71 least 80% (i.e., 10 out of 13) of the GCMs agree on the sign of the change.

72

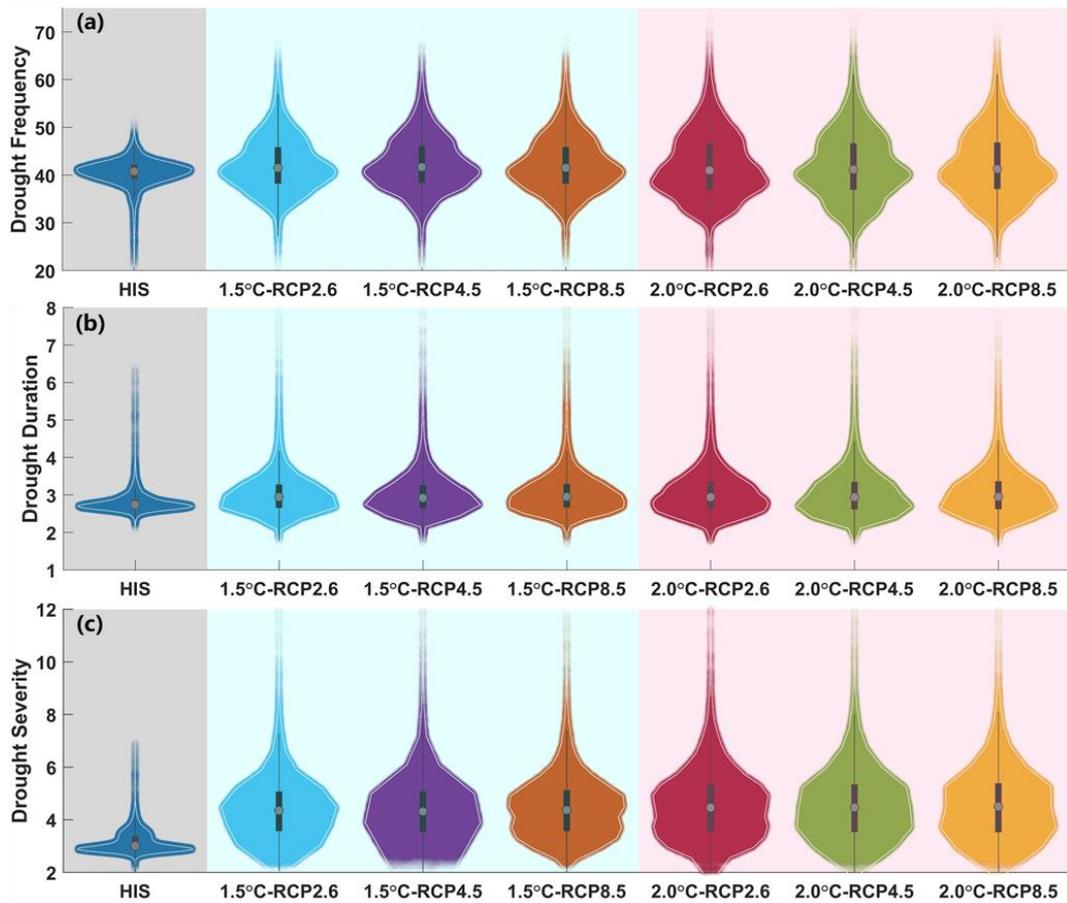

73

74 **Fig. 5. Projected changes in drought duration and severity between the 1.5°C and**  
 75 **2.0°C warming target**

76 Maps of the relative changes (%) in the multi-model ensemble mean drought duration  
 77 (a,c,e) and drought severity (b,d,f) from the 1.5°C to the 2.0°C warming target under  
 78 RCP2.6, RCP4.5, and RCP8.5. (g,h,i) Zonal results for drought duration and severity  
 79 in 1° latitude bin. The stippling (a-f) is shaded for areas where at least 80% (i.e., 10 out  
 80 of 13) of the GCMs agree on the sign of the change.

81

82

83

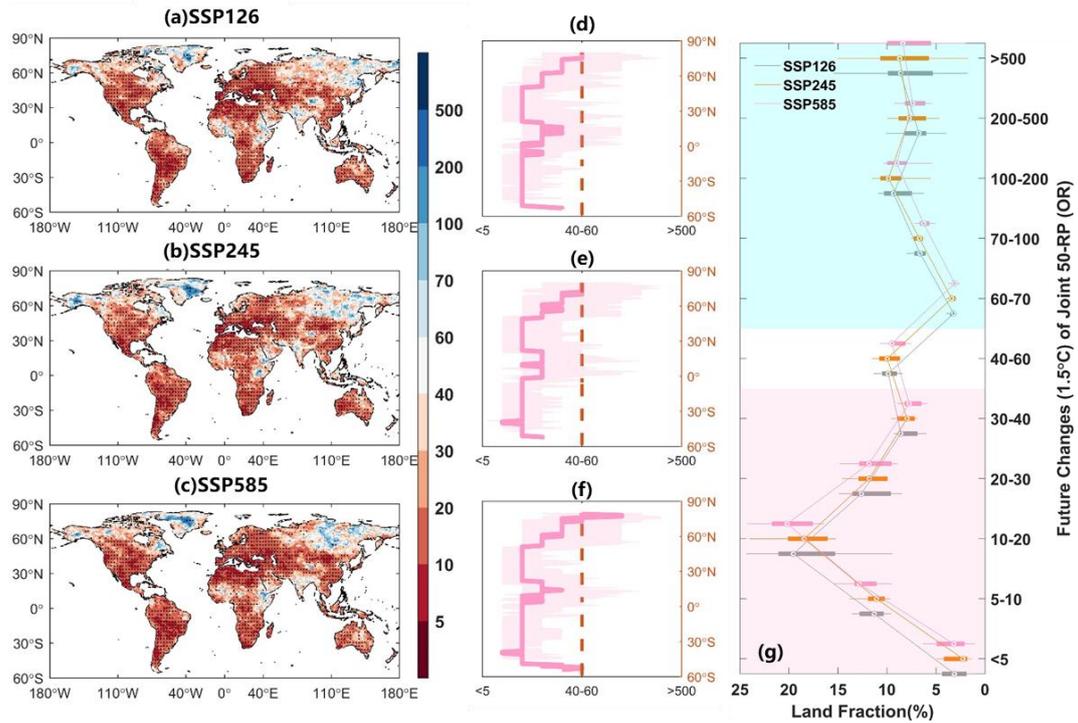

84 **Fig. 6. Distributions for drought characteristics under different time periods**

85 Distributions in the multi-model ensemble mean drought frequency (a), drought

86 duration (b) in months, and drought severity (c) across global land areas for the

87 reference period (1976-2005), the 1.5°C, and the 2.0°C warming target, respectively.

88

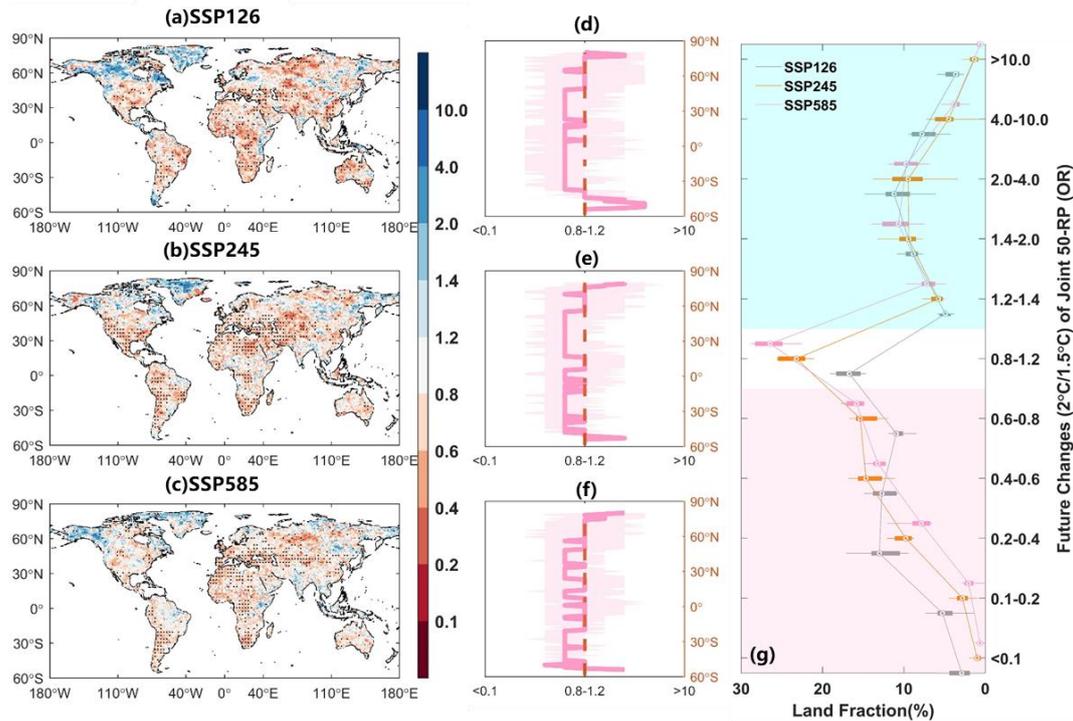

89

90 **Fig. 7. Projected changes in joint 50-year return periods of droughts under the**  
 91 **1.5°C warming target**

92 Projected GCMs median changes in joint 50-year return periods of droughts (duration  
 93 and severity) from the reference period to the 1.5°C warming target under SSP126,  
 94 SSP245, and SSP585. (d,e,f) Zonal results in each 1° latitude bin; (g) Global land  
 95 fraction subject to drought risk changes of different magnitudes under three scenarios.  
 96 For an individual climate model output, the land fraction is calculated by using the ratio  
 97 of grid counts located at certain extent (e.g., <5) divided by the world land grid counts  
 98 (excluding Antarctic). Each box is stemmed from the 13 climate models results and the  
 99 circle in each box represents the multi-model ensemble median results.. The stippling  
 100 (a-c) is shaded for areas where at least 80% (i.e., 10 out of 13) of the GCMs agree on  
 101 the sign of the change.

102

103

104

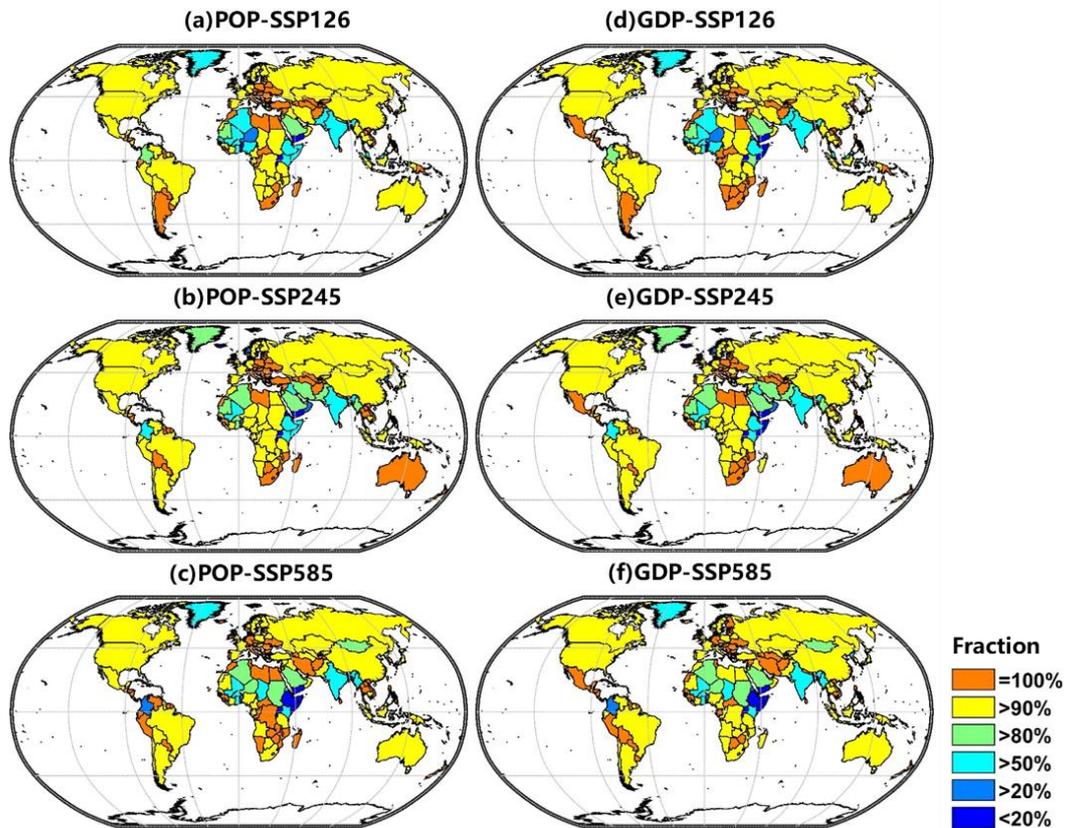

105 **Fig. 8. Projected changes in joint 50-year return periods of droughts between the**  
 106 **1.5°C and 2.0°C warming target**

107 Projected GCMs median changes in joint 50-year return periods of droughts (duration  
 108 and severity) from the 1.5°C to the 2.0°C warming target under SSP126, SSP245, and  
 109 SSP585. (d,e,f) Zonal results in each 1° latitude bin; (g) Global land fraction subject to  
 110 drought risk changes of different magnitudes under three scenarios. For an individual  
 111 climate model output, the land fraction is calculated by using the ratio of grid counts  
 112 located at certain extent (e.g., <5) divided by the world land grid counts (excluding  
 113 Antarctic). Each box is stemmed from the 13 climate models results and the circle in  
 114 each box represents the multi-model ensemble median results. The stippling (a-c) is  
 115 shaded for areas where at least 80% (i.e., 10 out of 13) of the GCMs agree on the sign  
 116 of the change.

117

118

119

121

122 **Fig. 9. National population and GDP fraction exposing to more frequent severe**  
 123 **droughts under the 1.5°C warming target**

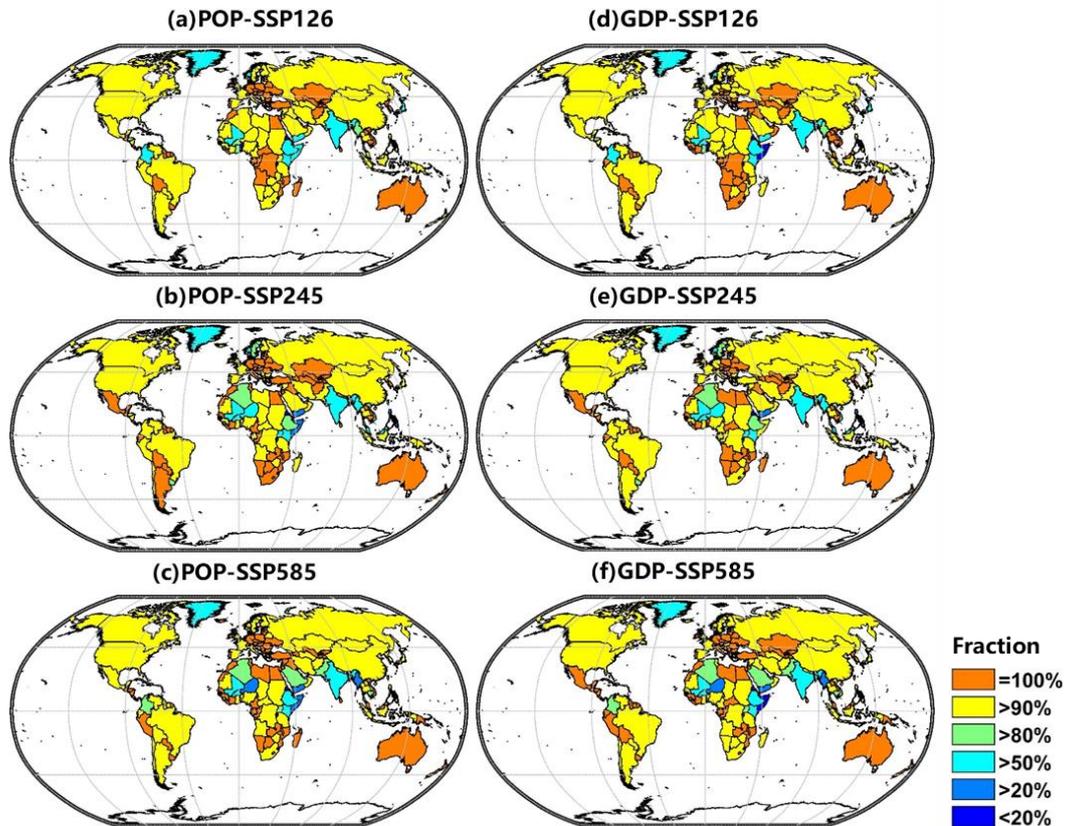

124 Maps of the population (**a,c,e**) and Gross Domestic Product (GDP) (**b,d,f**) fractions  
 125 that exposed to increasing drought risks from the reference period to the 1.5°C  
 126 warming target under SSP126, SSP245, and SSP585 scenarios. The color-bar in the  
 127 right side represents six ranks of the population and GDP fractions.

128

129

130

131

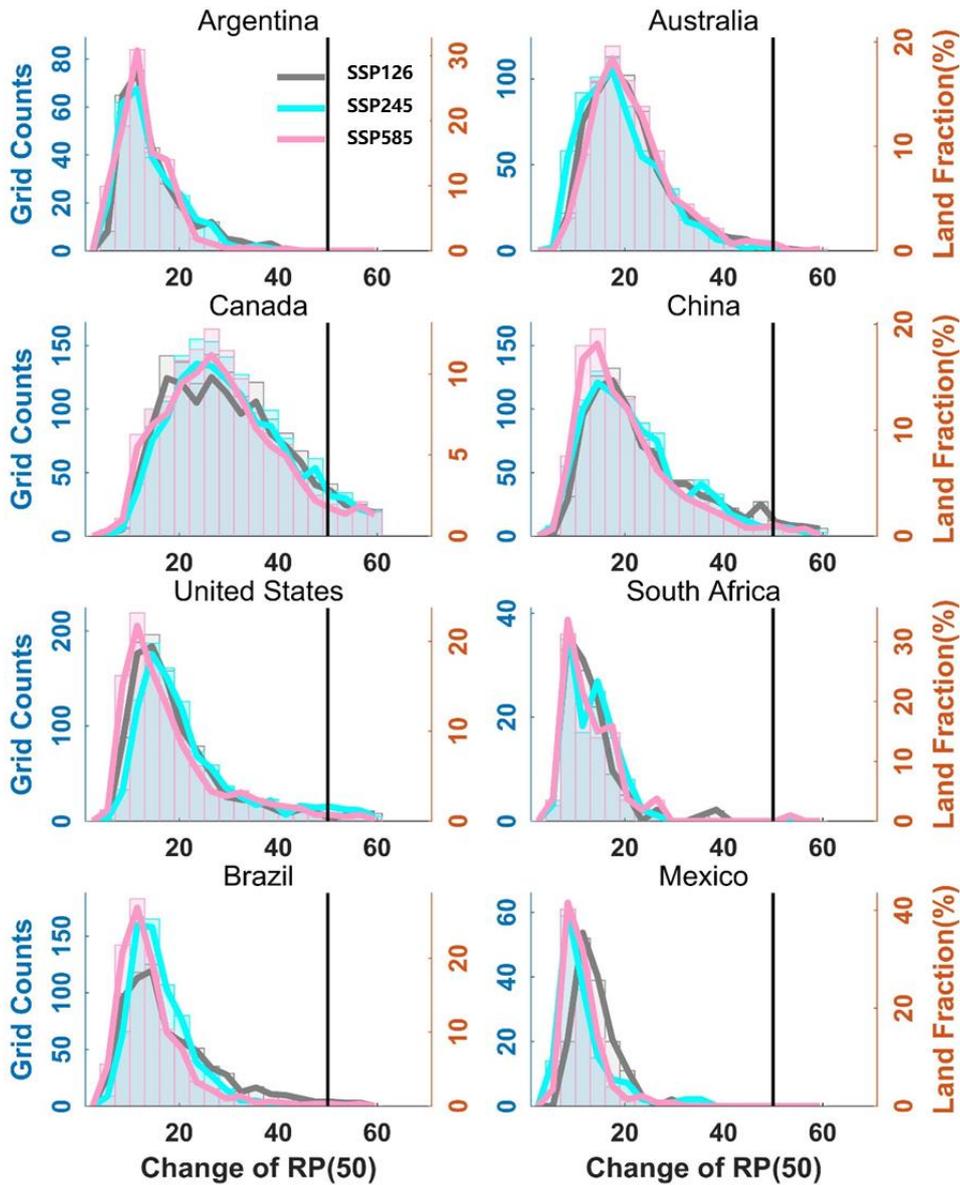

133

134 **Fig. 10. National population and GDP fraction exposing to more frequent severe**  
 135 **droughts under the 2.0°C warming target**

136 Maps of the population (**a,c,e**) and Gross Domestic Product (GDP) (**b,d,f**) fractions that  
 137 exposed to increasing drought risks from the reference period to the 2.0°C warming  
 138 target under SSP126, SSP245, and SSP585 scenarios. The color-bar in the right side  
 139 represents six ranks of the population and GDP fractions.

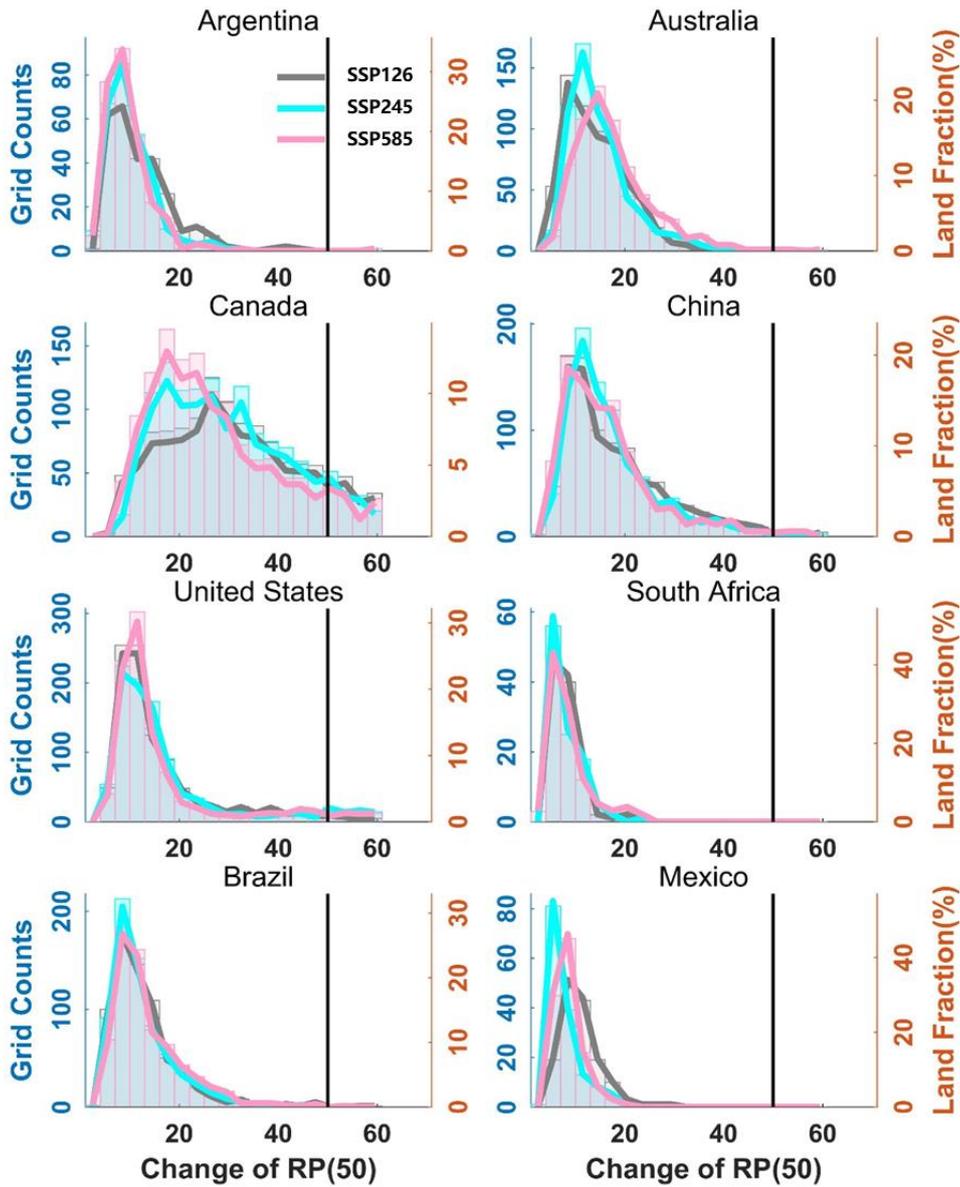

140

141

142 **Fig. 11. Projected changes of drought risks for 8 typical drought-prone countries**  
 143 **under the 1.5°C warming target**

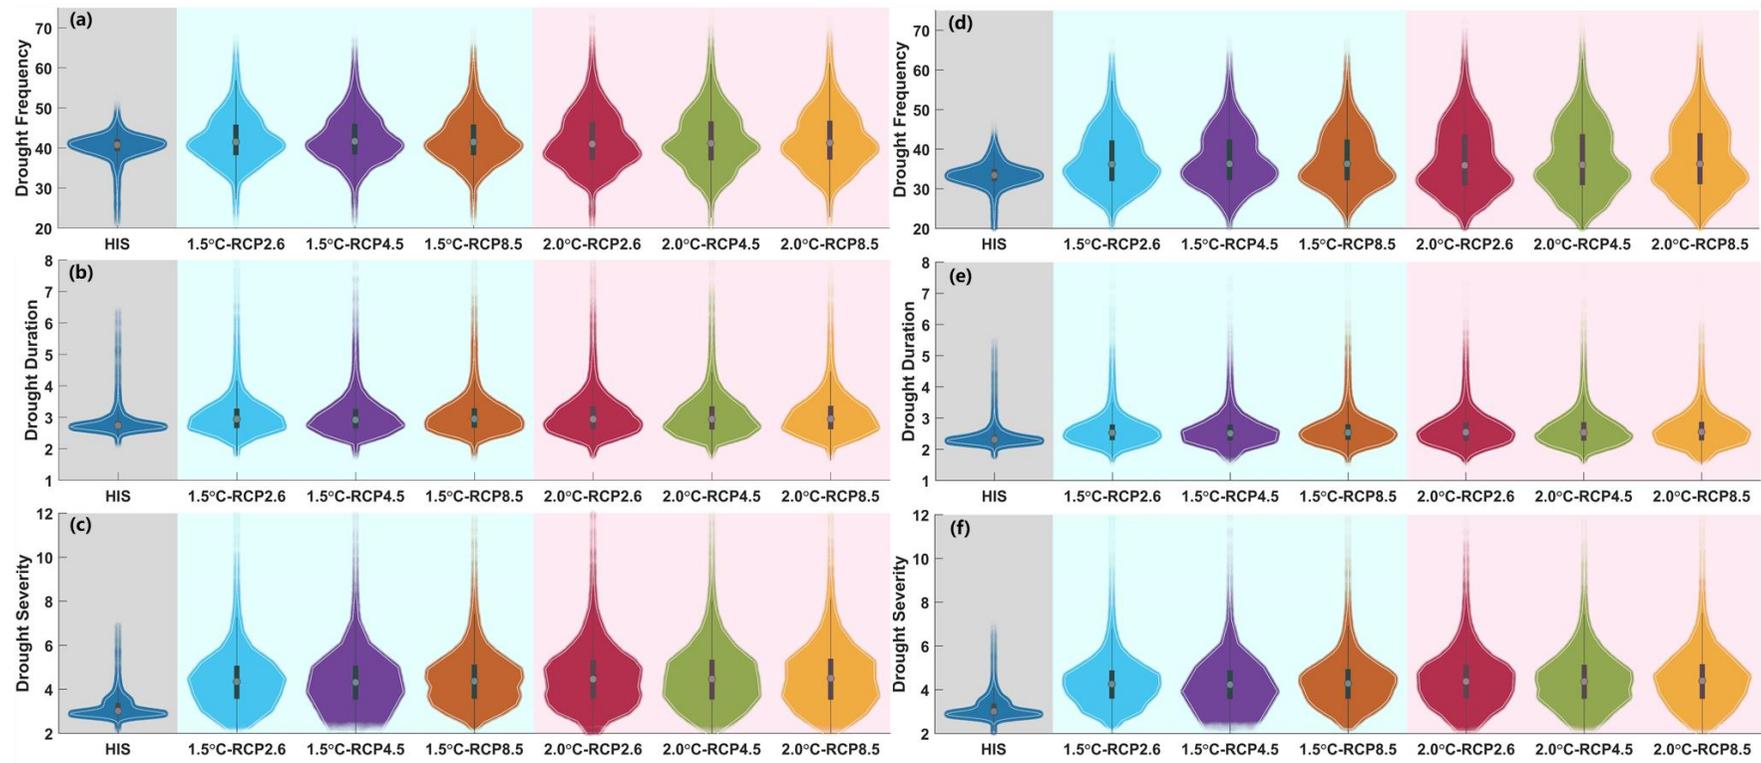

144 Projected GCMs median changes in joint 50-year return periods of droughts (duration  
 145 and severity) as a function of land fraction for 8 typical drought-prone countries from  
 146 the reference period to the 1.5°C warming target under RCP2.6, RCP4.5, and RCP8.5.

147

148 **Fig. 12. Projected changes of drought risks for 8 typical drought-prone countries**  
 149 **under the 2.0 °C warming target**

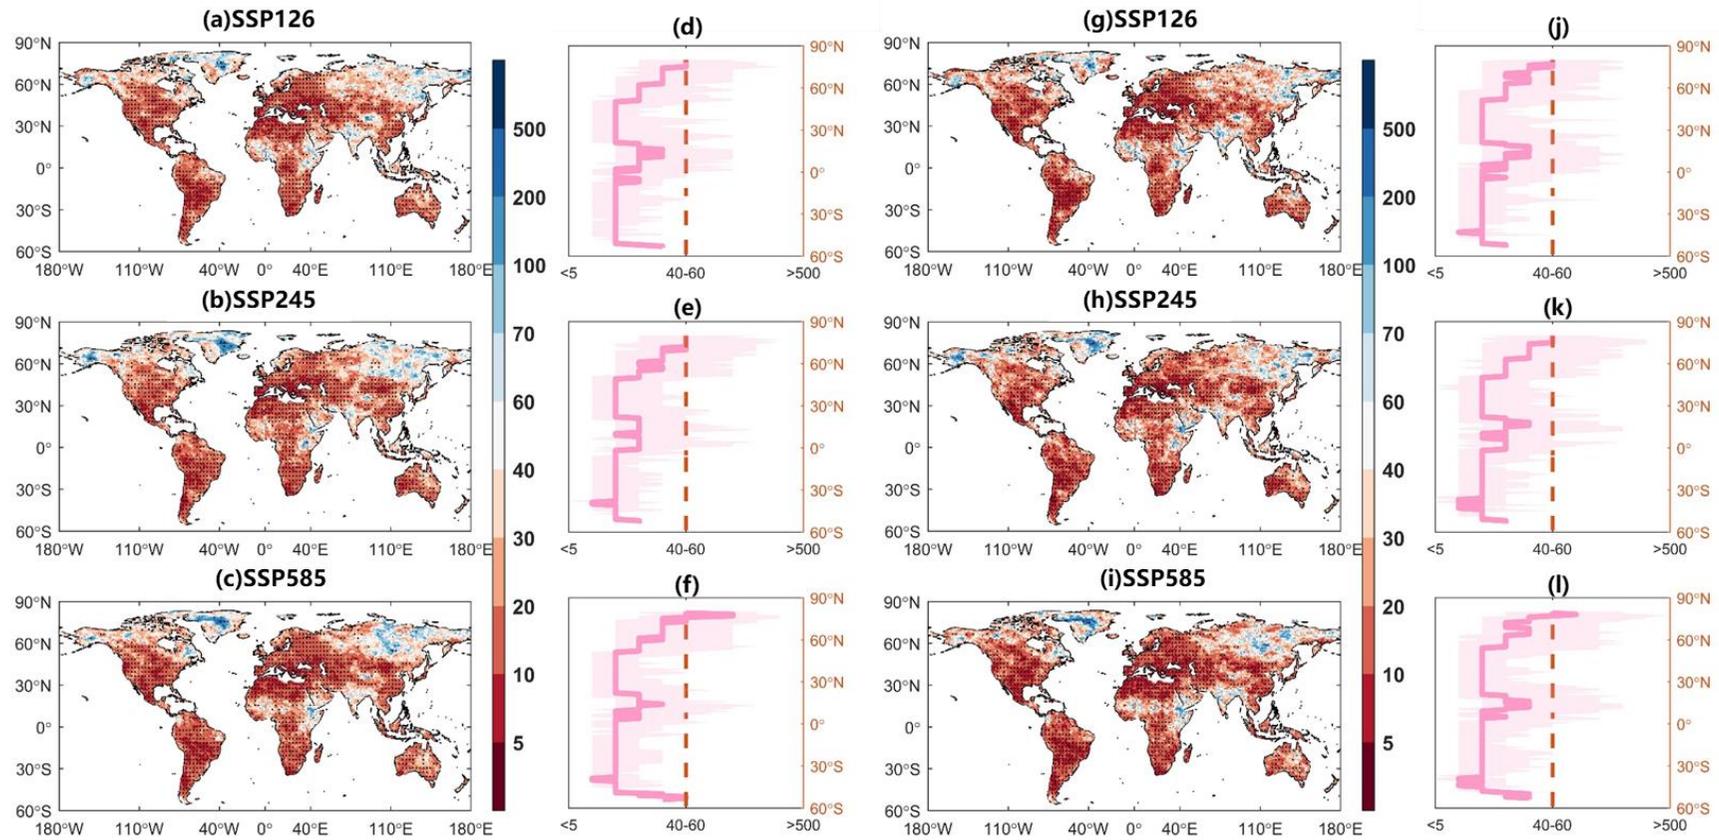

150 Projected GCMs median changes in joint 50-year return periods of droughts (duration  
 151 and severity) as a function of land fraction for 8 typical drought-prone countries from  
 152 the reference period to the 2.0°C warming target under RCP2.6, RCP4.5, and RCP8.5.
