1. Abstract

Natural risk studies such as flood risk assessments require long series of weather variables. As an alternative to observed series, which have a limited length, these data can be provided by weather generators. Among the large variety of existing ones, resampling methods based on analogues have the advantage of guaranteeing the physical consistency between local variables at each time step. However, they cannot generate values of predictands exceeding the range of observed values. Moreover, the length of the simulated series is typically limited to the length of the synoptic meteorology records used to characterize the large-scale atmospheric configuration of the generation day. To overcome those limitations, the stochastic weather generator proposed in this study combines two sampling approaches based on atmospheric analogues: 1) a synoptic weather generator in a first step, which recombines days in the 20th century to generate a 1,000-year sequence of new atmospheric trajectories and 2) a stochastic downscaling model in a second step, applied to these atmospheric trajectories, in order to simulate long time series of daily regional precipitation and temperature. The method is applied to daily time series of mean areal precipitation and temperature in Switzerland. It is shown that the climatological characteristics of observed precipitation and temperature are adequately reproduced. It also improves the reproduction of extreme precipitation values, overcoming previous limitations of standard analog-based weather generators.

2. Introduction

Increasing the resilience of socio-economic systems to natural hazards and identifying the required adaptations is one of today’s challenges. To achieve such a goal, one must have an accurate description of both past and current climate conditions. The climate system is a complex machine which is known to fluctuate at very small time scales but also at large ones over multiple decades or centuries (Beck et al. 2007). It is necessary to study meteorological series as long as possible in order to catch all sources of variability and fully cover the large panel of possible meteorological situations. Regarding weather extremes, the same need arises as estimating return levels associated to large return periods cannot be successfully done without long climatic records (e.g. Moberg et al., 2006; Van den Besserlaar et al., 2013). This comment also applies to all statistical analyses on any derived variable, such as river discharge, for which multiple meteorological drivers come into play and for which extreme events correspond to the combination of very specific and atypical meteorological conditions.
Using weather generators, long simulations of weather variables provide accurate descriptions of the climate system and can be used for natural hazard assessments. Among the large panel of existing weather generators, stochastic ones are used to construct, via a stochastic generation process, single or multisite time series of predictands (e.g. precipitation, temperature) based on the distributional properties of observed data. These characteristics, and consequently the weather generator parametrisation, are usually determined on a monthly or seasonal basis to take seasonality into account. They can also be estimated for different families of atmospheric circulation, often referred to as weather types. A state of the art of the most common methods which have been used for the downscaling of precipitation (single or multi-site) is presented in Wilks (2012) or in Maraun et al., (2010). More recent publications gather detailed reviews of some sub-categories of weather generators (e.g. Alliot et al., 2015 for hierarchical models). An increasing number of studies focuses on the generation of multivariate and/or multi-site series of predictands (e.g. Steinschneider and Brown, 2013; Srivastav and Simonovic, 2015; Evin et al. 2018a; Evin et al. 2018b). Stochastic weather generators are able to produce large ensembles of weather time series presenting a wide diversity of multiscale weather events. For all these reasons, they have been used for a long time to enlighten the sensitivity and possible vulnerabilities of socio-eco-systems to the climate variability (Orlowsky et al. 2010) and to weather extremes.

Another family of models used for the generation of weather sequences is the analogue method. Since the description of the concept of analogy by Lorenz (1969), the analogue method has gained popularity over time for climate or weather downscaling. This analogue model strategy has been applied in many studies (Boe et al., 2007; Abatzoglou and Brown, 2012; Steinschneider and Brown 2013) and has been used to address a wide range of questions from past hydroclimatic variability (e.g. Kuentz et al, 2015; Caillouet et al., 2016) to future hydrometeorological scenarios (e.g. Lafayse et al., 2014; Dayon et al., 2015). The standard analogue approach hypothesises that local weather parameters are steered by synoptic meteorology. A set of relevant large scale predictors is used to describe synoptic weather conditions. From the atmospheric state vector, characterizing the synoptic weather of the target simulation day, atmospheric analogues of the current simulation day are identified in the available climate archive. Then, the analogue method makes the assumption that similar large scale conditions have the same effect on local weather. The local or regional weather configuration of one of the analogue days is then used as a weather scenario for the current simulation day. The key element of the analogue method is that it does not require any assumption on the probability distributions of predictands. This is a noteworthy advantage for predictands, such as precipitation, which have a non-normal distribution with a mass in zero. Most of the studies using analogues focused on precipitation and temperature either for meteorological analysis (Chardon, 2014; Daoud, 2016), or as inputs for hydrological simulations (Marty, 2012; Surmaini et al., 2015). Nevertheless, analogues are increasingly used for other local variables such as wind, humidity (Casanueva et al., 2014) or even more complex indices (e.g. for wild fire, Abatzoglou and Brown, 2012). When multiple variables are to be downscaled simultaneously, another major advantage of the analogue method is that the different predictands scenarios are physically consistent and the simulated weather variables are bound to reproduce the correlations between the variables (e.g. Raynaud et al., 2017) and sites (Chardon et al., 2014). Indeed, when analogue models use the same set of predictors (atmospheric variables and analogy domains) for all predictands, all surface weather variables and sites are sampled simultaneously from the historical records, thus preserving inter-site and inter-variable dependency.

The two simulation approaches (stochastic weather generators and analog methods) described above present some important advantages for the generation of long weather series but also some sizeable drawbacks. Indeed, stochastic weather generators rely on strong assumptions on the statistical distributions of predictands. Identifying the relevant mathematical representations of the processes and achieving a robust estimation of their parameters can be difficult, especially if the length of the meteorological records is short. Modelling the spatial-temporal dependency between
variables/sites is an additional challenge. Conversely, for the analogue-based approaches, the identification of relevant atmospheric variables providing good prediction skills is not straightforward. The limited length of local weather records is also a critical issue since resampling past observations restricts the range of predicted values. In particular, the simulation of unobserved values of predictands is not possible. This can be problematic if one is interested in estimating possible extreme values of the considered variable. Furthermore, the information on synoptic atmospheric conditions required by analog methods are generally coming from atmospheric reanalyses, which also have a limited temporal coverage (e.g. from the beginning of the 20th century for ERA20C, Poli et al., 2013) and from the mid-19th century for 20cr (Compo et al. 2011). The length of the generated time series is thus typically bounded by the length of the reanalyses.

In this study we propose a weather generator (hereafter SCAMP+) building upon the SCAMP approach presented by Chardon et al. (2018) and making use of reshuffled atmospheric trajectories, following some of the developments by Buishand and Brandsma (2001) and You et al. (2014). The weather scenarios generated by SCAMP being limited by the coverage of the climate reanalyses, the SCAMP+ model extends the pool of possible atmospheric trajectories. Using random transitions between past atmospheric sequences, SCAMP+ generates unobserved atmospheric trajectories, on which the 2-stage SCAMP approach can be applied. By exploring a wide variety of atmospheric trajectories, SCAMP+ introduces some additional large-scale variability which improves the exploration of possible weather sequences. In addition, as done in SCAMP (Chardon et al., 2018), the SCAMP+ approach includes a simple stochastic weather generator which is estimated, for each generation day, from the nearest atmospheric analogs of this day. These two steps (random atmospheric trajectories and random daily precipitation/temperature values) improve the reproduction of extreme values, overcoming previous limitations of analog-based weather generators, usually known to underestimate observed precipitation extremes.

These developments are carried out for the exploration of hydrological extremes (extreme floods) of the Aare River basin in Switzerland (Andres et al. 2019a,b). Meteorological forcings, i.e. temperature and precipitation, are thus simulated to be used as inputs of a hydrological model, for different sub-basins of the Aare river basin. Meteorological simulations from SCAMP+ have been used in the Swiss EXAR project and have proven its ability to estimate the discharge values associated to very large return periods on the Aare River. In section 2, we describe in details the test region, the data and three simulation approaches (a classical analogue method, referred to as ANALOGUE, SCAMP and SCAMP+). Section 3 presents the main results on both climatological characteristics and extreme values. Section 4 sums up the main outputs of this study and proposes some further developments and analysis.

3. Data and Method

3.1 Studied region

This study is carried out on the Aare River basin which covers almost half of Switzerland (17,700 km²). The topography varies greatly within the basin with, on one hand, high mountains on its southern part (maximum altitude of 4270 m, Finsteraarhorn) and on the other hand, plains on the northern part (minimum altitude of 310 m). These different characteristics coupled with the basin being located at the crossroads of several climatic European influences give a wide diversity of possible weather situations across the year.
3.2 Atmospheric reanalysis and local weather data

The application of the analogue method requires a long archive providing an accurate description of both past synoptic weather patterns and local atmospheric conditions. Indeed, a wide panel of meteorological situations available for resampling is necessary in order to identify the best analogs for the simulation (e.g. Van Den Dool et al., 1994; Horton et al., 2017). In most studies, synoptic situations are provided by atmospheric reanalyses. Here, we use the ERA-20C atmospheric reanalysis (Poli et al., 2013) which provide information on large scale atmospheric patterns on a 6 h basis from 1900 to 2010. Data are available at a 1.25° spatial resolution. More specifically, the set of predictors used for the identification of atmospheric analogues is made of the geopotential height at 500 and 1000 hPa, the vertical velocities at 600 hPa, large scale precipitation and temperature. The justification of these choices will be given in section 3.3.1.

The local and surface weather parameters of interest are retrieved from 105 weather stations for precipitation and 26 weather stations for temperature, which are spread out homogeneously over our target region, as presented on Figure 1. These data are available at a daily time step from 1930 to 2014. They have been spatially aggregated in order to obtain daily time series of mean areal precipitation (MAP) and temperature (MAT) for the Aare region. The three weather generators considered in this study aims at producing scenarios of daily time series of MAP and MAT. It can be noticed that many applications of analogue-based approaches produce simulations at specific weather stations. However, as shown by Chardon et al. (2016) for France, the prediction skill is significantly improved when the prediction is produced for areal averages, which motivates the generation of MAP and MAT values in this study.

Fig.1: The Aare River basin (red) and locations of the different precipitation (dots) and temperature (triangles) stations.
3.3 Description of the three models

This section presents the three different models considered and evaluated in this study.

3.3.1 ANALOGUE: Classical analogue model

The most basic model evaluated in this study, hereafter referred to as ANALOGUE, relies on a standard 2-level analogue method. For each day of the simulation period, a first set of analogue dates is selected based on the predictors described in Raynaud et al. (2017) which guarantees both inter-variable physical consistency and good predictive skills for 4 predictands (precipitation, temperature, solar radiation and wind). In the present work, the predictors are defined as follows:

- The first level of analogy is based on daily geopotential heights at 1000 hPa and 500 hPa (HGT1000, HGT500) as proposed by Horton et al. (2012) and Raynaud et al. (2017). From September to May, the analogy is based on the geopotential fields on both the current day D and its following day D+1 at 12UTC. Thereby, the motions of low-pressure systems and fronts are better described and the prediction skill of the method for precipitation is improved (e.g. Obled et al. 2002; Horton and Brönnimann, 2019). In summer, only the geopotential fields on the current day are used as no similar improvement could be found with a two-day analogy. 100 analogues are selected for each day of the target period.

- The predictors selected for the second level of analogy derive from the best predictors sets identified in Raynaud et al. (2017). From September to May, they are the vertical velocities at 600 hPa and the large scale temperature at 2 meters. In summer, the vertical velocities but also other predictors such as the Convective Available Potential Energy (CAPE) led to a rather poor prediction of precipitation due to the coarse resolution of the atmospheric reanalysis, which prevent it from providing an accurate simulation of convective processes. Consequently, large scale precipitation from the reanalysis has been used instead, resulting in predictive skills similar to the ones obtained for the rest of the year. This second analogy makes a sub-selection of 30 analogues within the 100 analogues identified in the first analogy level.

The dimensions and position of the different analogy windows used to compute the analogy measures are presented on Figure 2. They follow the recommendations for the analogy windows optimisation presented in Raynaud et al. (2017) for all predictors.

With this 2-step analogy, 30 scenarios of daily MAP and daily MAT are generated for each day of the simulation period (1900-2010). Combined with the Schaake Shuffle method described in section 3.3.4, the application of the ANALOGUE model leads to 30 scenarios of 110-year time series of daily MAP and MAT.
Fig. 2: Positions and dimensions of the analogy windows in the analogue model at both analogy levels. $Z_{500}$, geopotential at 500 hPa; $Z_{1000}$, geopotential at 1000 hPa; $V_{600}$, vertical velocities at 600 hPa; $P$, precipitation; $T$, temperature.

### 3.3.2 SCAMP: Combined analog / generation of MAP and MAT values

The SCAMP model enhances the previous approach ANALOGUE which is not able to generate daily values exceeding the range of observed precipitation and temperature. SCAMP combines the analogue method with a day-to-day adaptive and tailored downscaling method using daily distributions adjustment (Chardon et al. 2018).

For each prediction day, the following discrete-continuous probability distribution proposed by Stern and Coe (1984) is fitted to the 30 MAP values obtained from the atmospheric analogues of this day:

$$F_{y}(y) = (1 - \pi) + \pi \cdot F_{GA}(y|y > 0, \alpha, \beta),$$

where $\pi$ is the precipitation occurrence probability, $F_{GA}$ is the gamma distribution parameterized with a shape parameter $\alpha > 0$ and a rate parameter $\beta > 0$. The $\pi$ parameter is directly estimated by the proportion of dry days, and the parameters $\alpha, \beta$ of the gamma distribution are estimated by applying the maximum likelihood method to the positive precipitation intensities among the 30 MAP values. 30 MAP values are then sampled from the distribution model (1) in order to obtain unobserved values of precipitation, possibly beyond past observations. When there are less than 5 positive MAP intensities in the analogues, we simply retrieve the MAP analog values. This distribution
model corresponds to a simplified version of the combined analog/regression model described in Chardon et al. 2018 and we refer the reader to this paper for further information. Similarly, for each prediction day, a Gaussian distribution $F_N(\mu, \sigma)$ is fitted to the 30 MAT values obtained from the analogues. A sample of 30 new MAT values is then generated from this fitted Gaussian distribution. As for the ANALOGUE approach, the Schaaake Shuffle reordering method is applied to the daily scenarios obtained from SCAMP. 30 scenarios of 110-year time series of daily MAP and MAT are produced.

3.3.3 SCAMP+

As mentioned previously, the first limitation of the analogue method is related to the length of the synoptic weather information that is used to generate local predictands time series. In the present case, the length of time series that can be produced with the models ANALOGUE and SCAMP is limited to 110-year long weather scenarios.

In SCAMP+, we extend the archive of synoptic weather information by rearranging the synoptic weather sequences, thus creating new atmospheric trajectories, used in turn as inputs to SCAMP. This generation of new trajectories makes use of atmospheric analogues, following those of the principles proposed in the weather generators described by Buishand and Brandsma (2001) and Yiou et al. (2014). For any given day, the atmospheric synoptic weather is considered to have the possibility to change its trajectory. The main hypothesis of this generation module is that if two days $J$ and $K$ are close atmospheric analogues with atmospheric patterns heading in the same direction, then their “future” are exchangeable and one could jump from one atmospheric trajectory to the other. In other words, day $J+1$ is a possible future of day $K$ and conversely day $K+1$ is a possible future of day $J$. The probability $p$ to jump from one trajectory to any other is considered as a parameter to estimate.

The principle of a random atmospheric trajectory generation is sketched on Figure 3. In the present work, the only predictor involved to compare the synoptic atmospheric configuration between 2 different days is the geopotential height field at 1000 hPa, for both the present day and its followers. The spatial analogy domain is the one used in Philipp et al. (2010) for the identification of Swiss weather types. The first line of Figure 3 presents an observed atmospheric trajectory in HGT1000 from February 8th to February 12th 1934. On the February 9th, we look for analogues of the current day and its following day D+1. This is done to ensure that the two initial states are similar (high pressure system located over France on February 9th 1934 and on its analogue, January 28th 1921) and that the main features move in similar directions (high pressure system heading South-East on both February 10th 1934 and January 29th 1921).

Practically, the five best analogues of the current atmospheric 2-day sequence are identified and one of those sequences is then selected with a probability $p$ to generate the new day of the new trajectory. The same method is repeated for this new day to find its future day (as illustrated in Figure 3 for the sequence January 30th 1921 - February 12th 1925) and extend the new trajectory with...
one additional day. This process is repeated as long as necessary. In the present work, it was used to generate a 1000-year trajectory of daily synoptic weather situations. Rather large differences between the synoptic weather situation can be obtained after some days between the observed atmospheric sequence (e.g. February 12th 1934) and the random atmospheric trajectory (February 12th 1925). As we will show later on, such a method leads to higher weather variability at multiple time scales.

To insure that two consecutive days of the generated sequences belong to the appropriate season, the five 2-day analogue sequences are identified within a +/-15-day moving window centred on the calendar day of the target simulation day (e.g. all June days if the target day is xxxx-06-15th).

Fig. 3: Construction of a new 5-day atmospheric trajectory from an observed synoptic weather sequence. Each sub-figure presents the geopotential at 1000hPa on the domain of interest. The black squares and arrows give the new atmospheric trajectory and the blue shading highlights the two-day analogue that helps "changing of atmospheric direction".

The transition probability $p$ from one observed trajectory to another indirectly determines the level of persistency of synoptic configurations. In this study, it has been calibrated in order to guarantee a good climatology of the large scale atmospheric sequences. To do so, we analysed the mean frequency and duration of each of the 9 weather types proposed for Switzerland by Philipp et al. (2010) in the observed synoptic series and in different reconstructed ones for transition probability $p$ ranging from 1/10 (one transition every 10 days in average) to 1 (one transition per day in average). The results presented on Figure 4 shows that a transition probability of 1/7 is necessary to generate atmospheric trajectories that present a relevant persistency within each weather type.
Fig. 4: Mean persistency of each of the 9 weather types (indicated by the different circles in each panel), as defined by Philipp et al. (2010), in the observed time series and in the simulated ones for transition probabilities ranging from 1 to 1/10 for the generation of atmospheric trajectories.

The long time series of synoptic weather generated with the above approach is further used as inputs to the SCAMP generator described in the previous section. The SCAMP+ approach leads to 30 scenarios of daily MAP and MAT, each of these scenarios being based on the 1000-year random atmospheric trajectories sequence. The output of this approach, combined with the Schaake Shuffle method described in the next section, is thus composed of 30 scenarios of 1000-year time series of daily MAP and MAT.

3.3.4 Temporal consistency: Application of the Schaake Shuffle

For each model (ANALOGUE, SCAMP and SCAMP+), 30 scenarios of daily MAP and MAT are produced. To improve the temporal/physical consistency between two consecutive days or between the temperature and precipitation scenarios (partially induced by the synoptic weather series), we use the Schaake Shuffle method initially proposed by Clark et al. (2004). This method makes use of both the inter-variable physical and the intra-variable temporal consistency in observations to combine, at best, the outputs of any weather generator and reconstruct consistent predictands time series. It is particularly useful if one is interested in generating relevant precipitation accumulation scenarios over several days. A full description of the Schaake Shuffle method can be found in Clark et al. (2004) and some applications can be found in Bellier et al. (2017) or in Schefzik (2017). Here, the Schaake Shuffle consists in modifying the sequences of MAP and MAT values, preserving the
association of the ranks of MAP and MAT and rearranging sequences between days \( D \) and \( D+1 \). Shuffled MAP and MAT sequences between consecutive days then have similar associations than what has been observed. In this study, we give priority to the temporal consistency of precipitation first. Temperature scenarios are recombined in a second step.

The different components of the models ANALOGUE, SCAMP and SCAMP+ are summarized in Figure 5.

Fig.5: Illustration of the different steps applied (grey boxes) with models ANALOGUE, SCAMP and SCAMP+. Outputs obtained after each step are indicated in red.

4. Results

This section presents different statistical properties of the scenarios obtained with the 3 models and discusses the performances of each model by comparison with observed statistical properties. For the sake of consistency between the outputs, we compare the 30 scenarios of 111 years obtained from ANALOGUE and SCAMP to 300 scenarios of 100 years from SCAMP+ (i.e. each scenario of 1,000 years is divided into 10 scenarios of 100 years).

4.1 Climatology

For both temperature and precipitation, the 3 models lead to an accurate simulation of their seasonal fluctuations (Figure 6). However, one can notice the slight overestimation of winter
temperature and an underestimation of July and August precipitation. SCAMP also tends to have a smaller inter-annual variability compared to ANALOGUE and SCAMP+. SCAMP+ also tends to have a smaller inter-annual variability compared to ANALOGUE and SCAMP+. SCAMP+ is able to generate seasonal values that significantly exceed the maximum values simulated by ANALOGUE and SCAMP (by 100 mm to 200 mm). This strongly suggests that a large part of the seasonal variability comes from the variability of the synoptic weather trajectories, the unobserved weather trajectories produced by SCAMP+ leading to a wider exploration of extreme seasonal values.

Fig. 6: Observed and simulated seasonal cycles of temperature and precipitation for ANALOGUE, SCAMP and SCAMP+. The grey shadings present the inter-quantiles intervals. Simulated seasonal cycles are obtained using 30 scenarios of 111 years from ANALOGUE and SCAMP and 300 scenarios of 100 years from SCAMP+. The distributions of seasonal precipitation amounts and seasonal temperature averages are presented in Figure 7. Whatever the season, the three models are able to generate drier and wetter seasons than the observed ones (Figure 7a). The very similar results obtained for ANALOGUE and SCAMP suggest that the daily distribution adjustments used in SCAMP do not introduce more variability at the seasonal scale. SCAMP+ is able to generate seasonal values that significantly exceed the maximum values simulated by ANALOGUE and SCAMP (by 100 mm to 200 mm). This strongly suggests that a large part of the seasonal variability comes from the variability of the synoptic weather trajectories, the unobserved weather trajectories produced by SCAMP+ leading to a wider exploration of extreme seasonal values.
Fig. 7a: Observed and simulated boxplots of seasonal precipitation amounts for ANALOGUE, SCAMP and SCAMP+ (Spring: March, April, May. Summer: June, July, August. Autumn: September, October, November. Winter: December, January, February).

The same comments can be made for spring and autumn temperatures (Figure 7b). For those variables however, SCAMP+ fails to simulate extremely hot summers or cold winters. This result is probably due to the non-stationary climate conditions experienced during the 20th century. Creating new atmospheric trajectories mixes synoptic sequences from the first half of the century with others from the early 2000s. The much coolest conditions prevailing until the 1980s result in few chances to generate seasonal temperature hotter than the 2003 summer for instance. This limitation will be further discussed in the next section.
Fig. 7b: Observed and simulated boxplots of mean seasonal temperature for models ANALOGUE, SCAMP and SCAMP+ (Spring: March, April, May. Summer: June, July, August. Autumn: September, October, November. Winter: December, January, February).

4.2 Daily Precipitations Extremes

As mentioned in section 1, simple analogue methods cannot simulate unobserved precipitation extremes at the temporal resolution of the simulation (here daily). Moreover, for higher aggregation durations, they also tend to underestimate observed precipitation extremes. Figure 8 presents the precipitation values obtained with the three models for different return periods (from 2 year to 200 years) and different aggregation durations (from 1 to 5 days).

Considering 1-day extreme events, ANALOGUE is obviously not able to generate precipitation accumulations that exceed the maximum observed one. Combining the analogue method with daily distribution adjustments (SCAMP) overcomes this issue with maximum values reaching 115 mm. SCAMP+ leads to similar results.
The large underestimation of daily extremes obtained with ANALOGUE leads to an important underestimation of 3-day and 5-day extremes. Despite a better simulation of daily values, SCAMP does not improve significantly the reproduction of 3-day and 5-day extremes. SCAMP+ outperforms both models for all durations, and generates precipitation extremes in agreement with observed extremes. Whatever the return period, the variability between the different 100-year scenarios is larger with SCAMP than with ANALOGUE and much larger with SCAMP+. This again suggests that 3 to 5-day extreme events can arise from atypical synoptic conditions, possibly not available in a 110-year long weather archive. Thanks to the random atmospheric trajectories, SCAMP+ is able to generate such conditions.

Fig.8: Return level analysis of extreme precipitation values associated to model ANALOGUE, SCAMP and SCAMP+ for accumulation over 1, 3 and 5 days. The grey shadings present the inter-quantiles intervals (30 x 111-year scenarios for models ANALOGUE and SCAMP and 300 x 100-year scenarios for SCAMP+).
5. Discussion

The different extensions of the classical analogue method introduced in this study aims at generating long regional weather time series without suffering from the main limitations of analogue models. Indeed, due to the limited extent of the observed time series and the impossibility to simulate unobserved daily scenarios, analogue models usually underestimate observed precipitation extremes. These limitations are relaxed by SCAMP+, the weather generator proposed in this study. SCAMP+ generates unobserved and plausible atmospheric trajectories, and, in addition, provides unobserved samples of temperature and precipitation using daily distribution adjustments. Such a generation process explores a larger weather variability at multiple time scales, which leads to a better reproduction of extremes.

SCAMP+ is obviously not free of limitations. A first issue is relative to the quality of observations used in the model, especially at the synoptic scale. ERA20C reanalyses used here are produced using sea level pressure and wind measurements only. This guarantees a certain quality of the geopotential at 1000 hPa. The quality of 500 hPa data and of the other predictors is conversely questionable (namely large scale temperature, precipitation and vertical velocities), as they do not beneficiate from the assimilation of observed data. This may impact the quality of the downscaling method. For instance, this could explain why the mean seasonal cycle of monthly precipitation is not well reproduced in our results (see for instance the underestimation of the mean precipitation in August). Using higher quality data is expected to partly address such limitations. Indeed, using ERA-Interim reanalyses (Dee et al, 2011) instead of ERA20C removes the biases and mis-reproductions mentioned above (not shown), a much larger panel of weather observations being assimilated in ERA-Interim. However, ERA-Interim covers a much smaller time period than ERA20C (roughly 50 years). Using ERA-Interim for our simulations would make the panel of observed synoptic situations much less representative of possible ones, and would impact the ability of our model to generate long-term climate variability. Similarly, the regional predictands time series are based on 105 weather stations for precipitation and 26 weather stations for temperature. The representativeness of this information is also questionable, especially if one is interested in looking at precipitation and temperature extreme events. However, this large number of stations leads to the best possible estimations of these regional variables that can be achieved currently.

Some other questions remain open, such as the difficulties encountered by SCAMP+ concerning the generation of very hot summers or very cold winters. It is very likely related to the temperature increase experienced over the 20th century, which appears clearly when looking at the hottest summers and the coldest winters. The new weather associations made by the random atmospheric trajectories are mixing days from the 1900s with other from the 2000s, their geopotential analogy being their only selection criteria. This could result in less chance to generate very hot summers (as observed in 2003) or very cold winters (as experienced in 1963). A possible improvement of the method could be to detrend the temperature data and perform the analysis presented in this study on "stationarized" temperature data (similarly to Evin et al., 2018b, see their section 2.2.1).

All in all, SCAMP+ weather generator paves the way for more developments and applications. As part of the EXAR project (see acknowledgments), the model was coupled with a spatial and temporal disaggregation model and fed a hydrological model in order to generate long series of discharge data
Additional evaluations on the inter-variable co-variability showed that the physical consistency between temperature and precipitation is well reproduced in our simulations and that the model thus efficiently simulates the precipitation phase and the statistical characteristics of liquid/solid precipitation. SCAMP+ has a low computational cost and is able to generate multiple weather sequences which are consistent with possible trajectories of large scale atmospheric conditions, which motivates future applications to other regions and local weather variables.

Data availability.
Precipitation and temperature data have been downloaded from Idaweb (https://gate.meteoswiss.ch/idaweb/), a data portal which provides users in the field of teaching and research with direct access to archive data of MeteoSwiss ground-level monitoring networks. However, the acquired data may not be used for commercial purposes (e.g., by passing on the data to third parties, by publishing them on the internet). As a consequence, we cannot offer direct access to the data used in this study. Atmospheric predictors are taken from the European Centre for Medium-Range Weather Forecasts (ECMWF) ERA20C atmospheric reanalysis (Poli et al., 2013), available at the following address: https://www.ecmwf.int/en/forecasts/datasets/reanalysis-datasets/era-20c.

Author contributions.
J. Chardon and D. Raynaud developed the different models considered here. D. Raynaud carried out the simulations, produced the analyses and the figures presented in this study. All authors contributed to the analysis framework and to the redaction.

Competing interests.
The authors declare that they have no conflict of interest.

Financial support. We gratefully acknowledge financial support from the Swiss Federal Office for Environment (FOEN), the Swiss Federal Nuclear Safety Inspectorate (ENSI), the Federal Office for Civil Protection (FOCP), and the Federal Office of Meteorology and Climatology, MeteoSwiss, through the project “Hazard information for extreme flood events on Aare River” (EXAR): https://www.wsl.ch/en/projects/exar.html.
